## BLAST AND CONCUSSION IN THE PRESENT WAR\*

JOHN F. FULTON, M.D.†

NEW HAVEN, CONNECTICUT

THE first definition of a bomb in the *Oxford Dictionary* is "a ball of wilde-fire." The Spaniards, it seems, quite early developed technics for burning enemy ships by projecting fire balls at their adversaries' sails and wooden decks; so that the first bombs were, strictly speaking, incendiaries. Later, mortars were developed for hurling explosive incendiaries. These explosive balls of fire became in the course of time less fiery and more highly explosive, and in the nineteenth century they came to be known as "bombshells." By the end of that century and during the last war, bombshells became just "shells," and the word "bomb" was reserved for explosives dropped from the air—or from the pocket of a discontented agitator.

The Nazis were the first to develop air bombing technics on a large scale: not only bombs of the high-explosive variety—screeching, bouncing and parachute bombs—but also "balls of wilde-fire" in the form of incendiaries, many of them diabolically arranged so that, when a firefighter attempts to smother them, they explode, showering hot burning magnesium in the faces of their victims. When attacking ships and objectives in England during the last two years, the Germans have used five types of high-explosive shells, the 50-kilo, 250-kilo and 500-kilo aerial bombs and the 500-kilo and 1000-kilo land mines.

### PHYSICAL CHARACTERISTICS OF BOMB DESTRUCTION

The 50-kilo bomb, which has been used in such profusion over the London area, produces destruction within a sharply circumscribed space for a width of 20 to 25 feet in brick dwelling houses, such as one encounters on Commonwealth Avenue or Marlborough Street, Boston; and if one of these houses were struck, one might expect, if

British example were followed, to see signs of "Business as Usual" on both sides of the 25 feet of gutted building. Similarly, when such a bomb strikes the middle of the street, it penetrates beneath the surface before exploding and then lifts up a heap of dirt over an area 20 to 30 feet in diameter and 3 to 5 feet in depth, depending on the character of the surface. The resulting crater presents a hazard to traffic. Taxicab drivers navigating in the blackout become accustomed to dropping into craters of this sort but are so skillful that they generally stop their cars when the back wheels are on the edge, quietly back out, and take another street. In England, bombing even of the 50-kilo variety is serious: since the winters are mild, the essential services are buried to a depth of only 2 or 3 feet. Almost invariably, therefore, a bombing episode in the street results in interruption of all five services—water, gas, electricity, sewerage and telephone; however, the demolition squads work with incredible speed, and generally within ten or fifteen hours all the services are repaired and the streets repaved. But all this requires a close-knit organization on the part of a dozen agencies and utilities, and I should think that the sooner such an organization is worked out on the eastern seaboard of the United States, the less the inconveniences of bombing would be felt when the time comes for the enemy to strike. We have the rich experience of the English people at our disposal. We have seen their mistakes. We have seen their magnificent reorganization on the basis of those mistakes, and I can only hope that we may profit by them.

The 250-kilo bomb creates greater havoc, but again the area of destruction is sharply circumscribed, being limited to 100 to 130 feet of four-story brick construction; if the bomb strikes in the middle of the street, the crater is 75 to 100 feet in width and 8 to 10 feet in depth. Windows may be broken at considerable distances—up to 200 or 250 yards—from the blast wave.

The 500-kilo or 1000-pound bomb, of which, fortunately, the Germans have been able to use very few, is incredibly destructive and may, if it happens to strike favorably, demolish the greater part of a city block. The effects of the blast wave in the air and through ground-shock may topple buildings at a distance of several hundred yards, and the results of a given detonation of this size of bomb are as bizarre and unpredictable as they are destructive. Much the same thing may be said for the land mine, which, coming down by parachute, may destroy the greater part of a city block. No details concerning the so-called "super-bomb" that the British are now using are available, but it is evidently "super" in the sense of having greater weight; if it is true that the British are using bombs weighing 1 to 2 tons, the havoc wrought in closely built areas must be colossal.

### BLAST INJURIES

The first detailed histologic study of the effects on the central nervous system of blast from high explosive shells is found in a paper by Mott,<sup>1</sup> which comprises the Lettsonian Lectures delivered before the Medical Society in London in February and March, 1916. During the Civil War, Mitchell, Morehouse and Keen<sup>2</sup> described the blast syndrome in unmistakable terms, but the neuron at that time was not an entity, since staining of the nervous system to aid in histologic scrutiny had scarcely begun. Mott draws attention to Sir Anthony Bowlby's<sup>3</sup> Bradshaw Lecture, *Wounds in War*, delivered in 1915, in which he remarks:

It must also be kept in mind that the mere explosive force of the gases of a large shell exercises great powers of destruction. The expansion of the gases is alone sufficient to kill, and in the only case in my experience in which an autopsy has been made, the brain was the seat of very numerous petechial haemorrhages.

This brain, which had been in Sir Arthur Keith's custody, was turned over in 1916 to Mott, who confirmed the existence of widespread petechial hemorrhage, but who also noted changes compatible with carbon monoxide poisoning. He cites, in addition, several nonfatal cases in which the explosion of large shells caused loss of consciousness without visible external signs of injury. In all these cases, the patient in question was propelled some distance by the blast wave, but there were no external injuries to suggest a primary blow on the head. Two of these cases may be cited:

A lieutenant under my care told me that he was in a communication trench when an aerial torpedo exploded close to him. He felt a great pressure against

him; it was soft but sufficiently powerful to knock him down unconscious. He did not know how long he was unconscious, but thinks it must have been an hour. When he recovered consciousness he got up and was helped away. His head felt as if it would burst, and ever since he has had a whizzing in the left ear and dizziness. Dreams of bombs and aerial torpedoes bursting. There was no parapet to blow down on him.

An R.A.M.C. officer at the battle of Ypres had a shell explode near him. He was not hit, but lay unconscious for six hours. He recollects the shock of the shell as he went out of the dressing-room. For some days he suffered with severe headache and soreness of back of head and down the spine; the lower extremities felt heavy, but there was no loss of feeling. He had retention of urine for a day only, and around the body there was a pain like an appendix pain. He rapidly recovered.

The first case is typical of hundreds of thousands in World War I. One must recall that men were engaged in trench warfare, and that they were protected from shell fragments by being submerged in trenches but were not protected from the blast wave of a shell exploding in close proximity. On recovery, those who were actually rendered unconscious by proximity to an exploding shell complained of headache, dizziness, lethargy and inability to concentrate—in short, they exhibited all the major signs and symptoms of the postconcussion syndrome of peacetime. In the parlance of the early days of the last war, they were said to be suffering from "shell shock" (von Sarbó<sup>4</sup>).

The problem of distinguishing psychogenic war neurosis from a case of organic concussion resulting from blast is delicate and often difficult, but I agree with Myers<sup>5</sup> that such a distinction is clearly essential. In a book recently published, he distinguishes between "shell concussion," a syndrome associated with organic injury to the brain, and "shell shock," a psychogenic syndrome due to the fears and fatigue of warfare. Often, however, the two syndromes are confused (Roubinovitch<sup>6</sup>).

It is interesting to trace the term "shell shock" in the various connotations that it acquired during World War I. Late in 1914 and during 1915, a soldier was said to have suffered shell shock when he was picked up unconscious and externally uninjured in the vicinity of an exploded shell. The usage was thus synonymous with "shell concussion." Stevenson,<sup>7</sup> however, in a short paper concerning the cause of death due to high-explosive shells in unwounded men, concluded that sudden death in these circumstances results from "concussion of the brain and interference with the functions of nerve centres which are essential to life, and the interruption of which means instant death." "I have seen many men," he continued, "home from the front who have been exposed to these explosions; all their symptoms and all their accounts of their experiences tend to confirm this belief, for it is to

the less severe injuries to these centres that the symptoms of men who recover and come home all point." Later, shell shock came to be applied more particularly to the cases of functional war neurosis.

Stevenson also refers to the interesting speculation of the French civil engineer, Arnoux,<sup>8</sup> who observed an exploded aneroid in the pocket of a French officer who had been killed by proximity to an exploding shell. The aneroid was repaired, and it was found that a sudden compression of 10,000 kilos per square meter was essential to disrupt it. Arnoux put forward the theory that, following such compression, gases in the blood and tissues expanded with bubble formation, and that men were killed by sudden massive air embolism. The aneroid observation is interesting, but the attempt to explain death as due to bubble formation was far fetched, since it did not take into consideration the rate at which gases dissolve under pressure, and the slow rate at which resolution occurs when pressure is diminished.<sup>9</sup>

To Mott<sup>1</sup> must be given the credit for having first emphasized the significance and likelihood of carbon monoxide poisoning in the vicinity of an exploding shell, especially one exploding in a confined space. Oxygen is absorbed by the explosion, carbon monoxide is liberated, and many of the so-called "deaths from blast" have been shown to be due to carbon monoxide poisoning of persons unconscious or pinioned under debris. The importance of carbon monoxide poisoning has lately been re-emphasized in connection with bombing injuries among civilians in England and Germany. However this may be, death from primary blast is a clinical entity that requires close study, because of its intimate connection with concussion and with the postconcussion syndrome of neuropsychiatry.

The general subject of blast injuries is discussed under four headings: the physics of the blast wave, the effects of blast on animals, the effects of blast on man, and suggestions concerning therapy.

### Physics of Blast Wave

Bernal,<sup>10</sup> of Cambridge, England, has given the best general account of the physical characteristics of a high-explosive wave. In material of high density and small elasticity, the wave travels slowly; where density is small and elasticity great, as in air, the wave travels at great speed. The high pressures created by bomb explosions cause an enormous velocity of wave transmission in air, but the rate of movement diminishes rapidly as the wave proceeds and there is also a marked change in the shape of the wave as it progresses. The pressure in some waves rises immediately to its peak and then falls off gradually and is followed by a phase of less than atmospheric pressure, that is, the negative phase (Fig. 1). The generation of this steep-fronted wave is very similar to that of the waves that break on the seashore. The high-

pressure phase of the disturbance, which always travels faster than the low-pressure phase, gets to the front just as the top of a wave on the sea, being held back less than the base by the friction of the sand, moves forward and ultimately breaks the wave.

This steep-fronted wave, sometimes known as the "shock wave," is responsible for blast and also for some of the bizarre effects of high explosives, such as the smashing of windows and doors at a

FIGURE 1. Figures Showing the Progress of a Blast Wave from a Small Charge of Powder (Bernal<sup>10</sup>).

distance. Pressure values of 5 to 10 pounds per square inch will break most windows, but blast pressures must rise to 6 atmospheres, or 100 pounds per square inch, before endangering a human being. This means that, to be injured by primary blast, a human being must be very near the site of the explosion. Zuckerman's<sup>11</sup> data on animals suggest that, at a distance of 30 feet from a 50-kilo bomb, a human being would be entirely safe from the direct effects of blast; published data concerning individual bombing episodes in which blast injuries have occurred in man support this deduction. With the large bombs, such as the 250-kilo and 500-kilo ones, the blast wave is more intense and travels farther.

Another aspect of bomb explosion concerns the blast wave in the earth, the so-called "ground

shock." Dropped from a great height, bombs generally penetrate some distance into the earth, the depth varying with the character of the surface. As previously mentioned, a 50-kilo bomb makes a crater of 20 to 30 feet in a dirt road. The sequence of events has been diagrammatically indicated by Bernal<sup>10</sup> (Fig. 2). A ground wave

difference of 2 or 3 feet often determining the question of life or death; there is a syndrome of primary shock characterized by collapse of the blood pressure in animals affected, but not killed, by the primary blast; there is complete absence of petechial hemorrhages or other intracranial lesions in the brains of animals exhibiting marked pri-

FIGURE 2. *The Series of Events Accompanying a Bomb Explosion in the Earth (Bernal<sup>10</sup>).*

has a high velocity, with an abruptly rising wave that may cause buildings to be shaken down at some distance from the site of the explosion.

#### *Effects of Blast on Animals*

The effects of primary air concussion due to shells or other explosives were not investigated experimentally until the end of World War I,<sup>12-15</sup> and to Hooker<sup>16</sup> must be given the credit for the most thorough experimental analysis as yet available. Men exposed to shell concussion, he pointed out, often developed a condition of shock that was unrelated to obvious trauma, since neither external nor internal wounds were clearly demonstrable. To investigate the phenomenon, a study was undertaken in the winter months of 1918-1919 at the Sandy Hook proving ground, with subsidy from the Committee on Shock of the National Research Council. In retrospect, it is highly significant and clearly a tribute to Hooker's insight that he regarded the condition of circulatory collapse following violent air concussion as indistinguishable from the circulatory collapse from primary shock that follows traumatic concussion in civil life. Hooker had opportunity to study the effects on frogs, cats and dogs, with the animals placed at varying distances from the muzzle of 10-inch and 12-inch guns and also from direct trinitrotoluene detonations. One dog, for example, placed 4 feet from the explosion of 4 pounds of trinitrotoluene, exhibited a fall in systolic blood pressure from 114 to 74 mm., and a fall in venous pressure from 8.7 to 6.2 mm. Hooker's studies emphasize four points: the fatal effects of primary blast occur in animals only relatively near the explosion, a

primary shock; and hemorrhagic lesions of the lungs and occasionally of other visceral organs are prevalent in animals subjected to blast. In his experience, however, the extent of the lung lesion bore little, if any, relation to the gravity of the concussion symptoms.

The experimental results of Hooker thus strongly suggest that the effects of primary blast in animals are closely similar to the effects of a blow on the head in an otherwise normal animal. He drew attention to the experimental studies of Githens and Meltzer,<sup>17</sup> and raised the question, without committing himself to an answer, whether the symptoms of air concussion were not ultimately similar to traumatic cerebral concussion.

Hooker's studies were published in 1924, but they aroused little comment. In the clinical literature during and after the war, there were many discussions of shell shock as an entity, and some authors, as already mentioned, used the term "shell concussion" to characterize symptoms resulting from primary blast.

New light on the problem has come from two groups of studies, one on blast and the other on experimental traumatic concussion of the head.

*Primary blast.* Zuckerman<sup>11, 18</sup> has given two detailed reports on the effects of primary blast in different animals, including mice, rats, guinea pigs, rabbits, cats, monkeys and pigeons. Seventy pounds of a high-explosive charge in paper containers so arranged that there would be no danger of injury from flying missiles was used as the source of the blast wave, and animals placed in well-anchored wire-mesh cages were arranged at

varying distances from the charge. As in the experiments of Hooker, there proved to be critical distance zones, which varied with the species of animal monkeys being considerably more resistant, for example, than rabbits. No monkeys were killed by a 70 pound charge at distances greater than 18 feet, and in no animal, rabbits included, were effects detectable at distances greater than 50 feet, at which the positive component of the blast wave averaged 6.3 pounds per square inch. Between 13 and 18 feet, almost all animals were killed when so placed that their body walls were affected by hydrostatic pressure alone. At these distances, the positive component of the blast wave that is, the hydrostatic pressure, varied between 126 and 63 pounds per square inch.

Between about 20 and 50 feet, no animals were killed, and those that survived showed little change in behavior. Those surviving between 18 and 21 feet often died within a few minutes to twenty-four hours after the blast; they exhibited widespread pathologic changes, the most conspicuous, as in Hooker's experiments, being hemorrhagic lesions of the lungs. But also, as in Hooker's experiment, there seemed to be no clear relation between the extent of the pulmonary lesions and the degree to which the animal had been affected by the blast wave. The pulmonary lesions are well illustrated in Zuckerman's<sup>18, 19</sup> later report.

Lesions were also found in other organs, including the epicardium of the heart, and very frequently in the large intestine, which proved to be the most susceptible, next to the lungs, to the effects of blast. The lungs, spleen and kidneys were often bruised or lacerated.

The nervous system was also carefully observed, especially in monkeys, the sections having been studied by Greenfield and also by Clark. The more important findings are summarized as follows.<sup>18</sup>

No changes were observed in the cortex, midbrain pons or medulla of monkeys subjected to pressures as high as 110 lb per square inch. On the other hand most monkeys exposed to high pressures show extradural hemorrhages in the thoracic spinal roots, which are sometimes continuous with hemorrhage along the intercostal nerves. In two animals that died, hemorrhage had occurred at the central ends of the posterior columns, and in the dorsal commissure. Furthermore, most animals have shown a zone of oedema, absent in controls, around the central canal, especially in the thoracic region but also in the cervical and lumbar cord. This oedema may involve both anterior and posterior commissural fibres.

Changes in nervous tissue are more pronounced in rabbits exposed to high pressures. Pial hemorrhages occur on the surface of the cortex, and hemorrhage from the tela choroidea, filling the ventricles, has been observed. Hemorrhages have not been seen, however, in either the grey or white matter of the brain.

Spinal-cord haemorrhages [in rabbits] are of the same kind as, but more severe than, [those] in the monkey.

It is conceivable that as a result of these lesions the sympathetic outflow may be interrupted and that sensory defects may occur as a result of oedema and pressure on the commissures.

Stewart, Russel and Cone<sup>20</sup> report on injuries to the central nervous system of a pheasant by blast during an air raid. The blasted pheasant was found 90 feet from the edge of a bomb crater, dazed and parietic after two large bombs had been dropped, but there was no way of determining how near the bird had been to the actual site of the explosion. It was in a catatonic state, and tended to retain any attitude in which it was passively placed. Microscopic examination of the nervous system showed congested capillaries of the forebrain, associated with numerous petechial hemorrhages, which were most numerous in the hypothalamic area. There were also massive hemorrhages in both lungs and numerous small hemorrhages in the heart. The report of Stewart and his co-workers is essentially in harmony with that of Zuckerman for the more serious cases of blast injury, but Zuckerman and Hooker insist that conspicuous symptoms referable to the nervous system may often be found with little recognizable histologic change.

**Concussion.** In previous experiments on concussion, such as the excellent studies of Pilcher,<sup>21</sup> Schaller et al<sup>22</sup> and Scott,<sup>27</sup> measured blows were delivered to an animal whose head was rigidly fixed, since anesthesia was employed, one criteria of concussion, namely, loss of consciousness, could not be appraised. The following clinical experience of Denny Brown<sup>24</sup> suggested that acceleration of the head in space was essential for the concussion syndrome, rather than a blow on the head per se. An automobile mechanic, when his head was solidly on the concrete floor, had the misfortune to have a car fall off the jack, and his head was pinioned against the floor by the car's differential. He suffered a severe compound fracture, but no symptoms of concussion, indeed, immediately after the accident, the man was unaware that he was seriously injured. In this case, there had been no movement of the head, merely a crushing blow. Similar cases have just been reported by Eden and Turner<sup>25</sup>. If, however, the head is struck when unsupported and is thus able to move, symptoms of concussion inevitably develop. Furthermore, if the head, when moving, is brought abruptly to a stop, deceleration occurs and is similarly effective in producing concussion. On the basis of this reasoning Denny Brown and Russell<sup>24</sup> devised a series of experiments in which a fixed head was struck with a pendulum moving

at velocities between 10 and 30 feet per second, the results being compared with those obtained with similar blows when the head was free to move. With the head fixed, blows that gave severe contusion and fractures of the skull failed to cause concussion. With the free head, three categories of symptoms developed, depending on the intensity of the blow, and usually appeared in the following sequence: shock, concussion and contusion.

**Shock.** When the blow is delivered at about 23 to 24 feet per second, the animal develops the classic symptoms of traumatic shock. The pulse rate slows for a time and then increases, the blood pressure falls, respirations become quick and shallow, and the animal becomes incapacitated for a period of several hours; but the knee jerks and the pinnal and corneal reflexes are unaffected. It is highly significant, especially in view of Hooker's<sup>16</sup> and Zuckerman's<sup>18, 19</sup> work on blast, that a blow on the head can of itself induce symptoms of generalized shock.

**Concussion.** A distinction is made between shock, as such, and symptoms of concussion, which develop when slightly heavier blows are delivered, that is, those struck at a velocity of 25 to 28 feet per second. Following these heavier blows, the corneal and pinnal reflexes are abolished for varying intervals, the resting posture (tonus) of the extensors disappears, and spinal reflexes may be altered or even temporarily abolished. A blow of this magnitude, if delivered to a conscious animal, renders it unconscious, whereas the blow causing shock does not necessarily cause unconsciousness.

The pathologic changes in the brain associated with shock and concussion blows have been carefully sought and have been proved wholly absent so far as ordinary microscopic examination is concerned. There are no petechial hemorrhages and no contused hemorrhagic areas in the medulla or cerebral hemispheres. The microscopic causes of the symptoms of concussion are still obscure, but no doubt they involve some basic intracellular disorganization of the neuron.

**Contusion.** When blows are delivered to the head at a rate greater than 28 feet per second, contusions usually develop in which hemorrhages occur beneath the site of the blow (or as a contrecoup at the opposite side of the head), and petechial hemorrhages are prone to develop, especially in the basal nuclei, brain stem and medulla. Age and other factors, however, affect the actual velocity essential for contusion.

The studies of Denny-Brown and Russell thus indicate that conspicuous concussion may be produced in animals without causing clearcut histologic changes. Studies of Hooker<sup>16</sup> and Zuckerman<sup>11</sup> prove that this is also true of blast concussion. Is there anything in common between direct traumatic concussion and blast concussion?

Zuckerman<sup>18, 19</sup> is of the opinion that lung damage is due to the physical impact of the blast wave against the thoracic wall rather than to sudden distention of the lungs by the positive component of the blast wave, or to a suction effect of the negative component of the blast wave. Such changes as occur in the central nervous system are like-

wise thought to be caused by sudden impact. There are obviously two components to be considered in the blast wave: the primary increase in atmospheric pressure to 100 pounds or more per square inch, and the rate of movement of the blast wave itself. Sudden increase of pressure might rupture the tympanic membrane, but from experience of caisson workers it is not likely that the pressure itself would cause concussion any more than a mechanical blow on a fixed head. A wave of moving pressure that gives acceleration of the body by virtue of its impact on the body wall—and hence imparts an acceleration to the body as a whole, including the head—reproduces in a very precise manner the type of acceleration or deceleration known to be essential for the traumatic-concussion syndrome.

Those who are surprised by the apparent lack of histologic change in cases of concussion will be interested to learn that de Gutiérrez-Mahoney,<sup>26</sup> of Nashville, Tennessee, has confirmed the results of Denny-Brown and Russell, finding that when the fixed head is struck there is in fact no detectable histologic change, but that when the head is given an acceleration by a corresponding blow and concussion results, a widespread demyelination of nerve tracts, followed by a transient appearance of fat droplets throughout the cerebral substance, can be detected; outspoken fat embolism may also result. The fat droplets and emboli tend to disappear entirely within three or four hours after the blow, and de Gutiérrez-Mahoney believes this to be the reason why fat embolism has not been previously demonstrated.

Fat embolism has assumed prominence in the present war, and there are many reports in the current literature, especially from England, concerning its incidence. In a group of 115 cases reported by Robb-Smith<sup>27</sup> in February, 1941, death was attributed to embolism in 25 per cent of cases. In a more recent discussion on fat embolism and the brain, Robb-Smith<sup>28</sup> and others who contributed to the discussion suggest that cerebral complications developing secondarily after an accident are due to the fat emboli that have passed through the lungs into the cerebral circulation. These may arise locally in contused tissues, such as a crushed long bone. Usually, the lungs separate out all the fat globules, but occasionally a pulmonary vein is torn so as to permit escape of fat into the systemic circulation. Robb-Smith states: "In systemic fat embolism the symptoms usually develop two to three days after the accident and are characterized first by delirium, which is frequently very violent, alternating with stupor which merges into coma. Localizing signs are usually absent or, if present, are chaotic. Hyperpyrexia is usual and it is not uncommon to find petechial haemorrhages in the skin of the neck, chest and arms, and their presence greatly facilitates diagnosis." He had not encountered cases in which cerebral fat embolism was attributable to direct traumatic concussion of the head.

### Effects of Blast on Man

High-explosive bombs and shells have been used more widely on civilian populations and at sea during World War II than in any previous conflict. When bombs or shells explode in a confined space, as in a building or on a ship, the blast effects are many times intensified. There is thus no more urgent problem connected with the present war than the analysis of blast and its effect on the human body. Despite this, available literature is scant, and research endeavor has been limited to a small group of investigators in England, who took up the problem to help in designing adequate air-raid shelters for protection from blast,<sup>20</sup> as well as from high-velocity fragments. Although this country has for two years been aware of the bombing of cities and shelling of ships on the high seas, nothing has been done toward investigating blast.

From English sources, especially from the reports of Dean, Thomas and Allison,<sup>30</sup> Falla,<sup>31</sup> Hadfield and his co-workers,<sup>32</sup> Hadfield and Christie,<sup>33</sup> Kretschmar,<sup>34</sup> Krohn,<sup>35</sup> Logan<sup>36</sup> and Thomson,<sup>37</sup> it is believed that death from un complicated primary blast in civilian areas is rare, but well authenticated cases have been reported especially in the recent and well-documented account of 17 cases by O'Reilly and Gloyne.<sup>38</sup> Un complicated cases of primary blast may, however, be relatively uncommon, since to be killed by its effects, the person must be very close to the explosion, that is, within 20 or 30 feet (50-kilo bomb). In these circumstances, the chances of being struck by the blast wave alone and not by splinters is somewhat remote. But there have been many thousands of cases in which primary blast and splinter injuries have coexisted. These have been especially common when a direct hit has been made on a crowded air-raid shelter. Similar episodes have occurred at sea,—in the shelling of crowded transports and warships,—and primary blast should therefore always be suspected in any bombing injury.

The histologic findings in man, so far as they have been described, are similar to those in Zuckerman's<sup>18</sup> monkeys subjected to blast waves of 100 pounds per square inch, namely, pulmonary hemorrhages, contusions and lacerations of other thoracic and abdominal viscera, minor changes in the central nervous system, and occasional areas of subpalp hemorrhage.<sup>39</sup> Evidently, as in animals, profound concussion can occur with little in the way of histologic effect.<sup>30</sup> Whether acute cerebral fat embolism exists in such cases has not been determined.<sup>40-42</sup>

### Therapy

It is not possible to discuss the difficult problems of therapy in cases of cerebral and pulmonary

concussion resulting from primary blast, but one general principle is clear. As more is learned about traumatic concussion in civil life, as well as concussion from blast, it becomes obvious that anoxia plays a large role in the total picture. Blood pressure tends to fall as a result of primary shock.<sup>21</sup> The recent German literature<sup>43</sup> on cerebral blood flow following concussion, moreover, indicates that cerebral circulation becomes diminished, and that the pulmonary damage is frequently accompanied by fat embolism. All these circumstances, in my opinion, indicate the need for oxygen therapy, and for measures designed to improve the systemic and especially the cerebral circulation.<sup>44</sup>

## ENTEROCOCCAL ENDOCARDITIS\*

### Report of Two Cases

DAVID SKINNER, M.D.,† AND JESSE E. EDWARDS, M.D.‡

BOSTON

OF the various bacteria causing subacute bacterial endocarditis, the enterococcus is encountered infrequently. Since we have recently had the opportunity of observing 2 patients with enterococcal endocarditis, it is of interest to review each case and the literature, with particular reference to the pathology and bacteriology.

Thirty-seven cases of enterococcal endocarditis have been reported with varying degrees of completeness in the accessible literature,<sup>1-28</sup> and mention has been made of several more.<sup>6, 29-40</sup>

The clinical course of these cases is not pathognomonic of their etiology; it is indistinguishable from that of the common subacute bacterial endocarditis due to *Streptococcus viridans*. From the blood stream of each of the 37 patients discussed, enterococci were recovered on one or more occasions. The shortest known duration of one of these cases was six weeks, the longest thirteen months, and that of half the cases was between two and three months. Of the 25 patients whose underlying cardiac lesions were given on the basis of clinical or anatomic evidence, 20 had rheumatic, 4 had arteriosclerotic, and 1 had syphilitic valvular disease.

Autopsies were performed on 17 of these 37 patients. In all autopsied cases the clinical diagnosis of subacute bacterial endocarditis was substantiated. In general, the additional findings were the usual ones of multiple embolic phenomena. Five patients had cardiac lesions of special interest. Four had severe myocardial damage characterized by replacement of the muscle fibers by scar tissue.<sup>3, 20, 23</sup> The coronary artery of 1 of these 4 cases was involved in a mycotic aneurysm.<sup>20</sup> In

the fifth patient, there was a small abscess in the myocardium.<sup>16</sup>

In 9 of the 17 cases in which autopsies were performed, an attempt was made to isolate the organism; in each, an enterococcus was cultured from the heart's blood or vegetations, or both. Smears or sections of the heart valves in 3 other cases disclosed gram-positive cocci in pairs and short chains. Enterococci were also recovered in cultures of various embolic abscesses in 5 of the cases.

The portal of entry of the infection was not discussed in 15 of the 37 cases. In 8, it could not be determined. The possible or probable portal of entry stated for the remainder was an infected finger in 1,<sup>2</sup> infected tonsils in 1,<sup>21</sup> the gall bladder in 2,<sup>16, 26</sup> the urinary tract in 2,<sup>8, 9</sup> septic abortion in 3,<sup>10, 17, 20</sup> and the gastrointestinal tract in five.<sup>7, 11, 13, 15, 19</sup> Each of the 2 patients in whom the portal of entry was the urinary tract had a proved enterococcal urinary-tract infection and a urethral stricture. Subsequent to surgical relief of the stricture, each patient developed enterococcal endocarditis. From the gall bladder of 1 of the 2 patients whose portal of entry was considered to be the biliary tract, enterococci were cultured at autopsy. Four of the 5 patients whose gastrointestinal tracts were involved had had acute gastroenteritis. In the fifth patient, autopsy disclosed ulcerations of the rectosigmoid. No bacteriologic studies of the possible portals of entry of the remaining cases were made.

Unfortunately, the characteristics of the organisms recovered were described in detail in so few cases that a comparison of the different strains is not possible. The antigenic properties of only one of the organisms were investigated.<sup>28</sup> It should be noted, however, that half the cases were re-

ported prior to the publication of Lancefield's<sup>41</sup> methods of classification

### CASE REPORTS

**CASE 1** A 72-year-old businessman presented himself on March 30, 1939, with the chief complaint of twice having passed blood at the end of urination.

The past history, which revealed that in 1915 he was refused life insurance because of a heart murmur, was otherwise noncontributory.

The patient was first seen in January, 1934, because

obese abdomen. On rectal examination, the prostate was greatly enlarged but soft. There were old blood and smegma about the corona and a moderate balanitis. His physical condition otherwise was essentially normal, not having changed appreciably during the 5-year interval.

Laboratory examinations disclosed a hemoglobin level of 100 per cent and a red-cell count of 5,250,000. A catheter specimen of urine was essentially normal. The blood nonprotein nitrogen level was 46 mg per 100 cc. An intravenous pyelogram showed normal function in each kidney and a large intravesicular prostate, with ele

FIGURE 1

*Photograph of the mitral valve in Case 1, showing the fairly large, irregularly deposited vegetations of bacterial endocarditis.*

he suffered a burning sensation in the rectum after defecation. There were no associated urinary symptoms. About 6 weeks later, he began to have a slight burning on urination and to feel uncomfortable. There was diurnal frequency of five or six times and no nocturia. Physical examination revealed a slight, apical, systolic, cardiac murmur, a blood pressure of 200/90, and a moderately enlarged but soft prostate. Proctoscopy yielded negative results. Laboratory data disclosed an essentially normal urine and peripheral blood, a negative Wassermann reaction, and blood sugar and nonprotein nitrogen levels within normal limits. Roentgenographic studies of the chest, gall bladder, gastrointestinal tract and kidneys were essentially negative.

Five years later, in March, 1939, the patient returned with the chief complaint of having twice passed approximately a tablespoonful of blood at the end of urinating clear, nonbloody urine. There was no associated pain or dysuria. The urinary stream had become somewhat smaller during the intervening 5 years.

Physical examination showed that the patient had gained considerably in weight and had developed a very

vation of the ureteral orifices, and back pressure into the ureters.

On April 6, a bilateral vasotomy and a one-stage suprapubic prostatectomy were performed under spinal anesthesia. A very large, vascular prostate was enucleated by the usual technique. The bladder wall was greatly hypertrophied, and the histologic appearance of the prostate was that of benign enlargement. The patient had an uneventful convalescence.

Two months after the operation, in June, the patient began to exhibit an evening temperature of 100 to 102°F. Throughout the rest of the day, he felt well and at no time had chills. There occurred an occasional slight swelling of the right ankle, which was considered to be due to a mild pelvic phlebitis. However, the fever persisted, and, early in July, a blood culture grew an organism that morphologically resembled a pneumococcus.

The patient was again hospitalized. He had no complaints except the evening fever. His general physical condition was essentially as before. The prostatectomy wound was well healed, and the blood pressure was 140/80. Urinalyses showed only an occasional leukocyte

in the sediment. The hemoglobin level was 70 per cent, the red-cell count 3,000,000, and the white-cell count 14,000. The blood nonprotein nitrogen level was within normal limits. A roentgenogram of the chest taken with a portable machine showed a prominent heart shadow but otherwise was not remarkable. A blood culture taken on July 19 grew organisms that were similar in appearance to those previously recovered and were identified as enterococci. Three carious teeth were extracted. From their roots, the same organisms were cultured. Sulfapyridine was given empirically until a blood level of 11.5 mg. per 100 cc. was obtained. Because there was no amelioration of the fever and because the blood nonprotein nitrogen level reached 60 mg. 100 cc., the drug was withheld.

The patient was allowed to go home, where he continued to exhibit an evening temperature of 100 to 102°F. He gradually failed. On December 20, the blood hemoglobin, erythrocyte and leukocyte levels were within normal limits. Blood cultures taken on December 28 again grew enterococci. The patient died on January 4, 1940.

**Autopsy.** An autopsy was performed 12 hours post mortem. Only the pertinent findings are given.

The heart was of normal size, weighing 400 gm. The myocardium was firm and yellowish to deep red. In the lateral wall of the left ventricle approximately 2 cm. from the apex was a focus 1 cm. in diameter in which the myocardium was distinctly yellow. The foramen ovale, measuring 3 mm. in diameter, was anatomically though not functionally patent.

The mitral, aortic and tricuspid valves were the sites of a bacterial endocarditis, the lesions being much more extensive on the mitral than on the other valves (Fig. 1). On the mitral valve, the vegetations, measuring 5 mm. in thickness, were attached to the auricular surface of each cusp and extended slightly along the adjacent chordae tendineae. The surfaces of the vegetations were irregular, and their color varied from yellowish brown to gray. Although friable, they showed foci of calcification, especially in their basal portions. On and near the corpora arantii of the aortic valve were small, gray, friable vegetations, the aggregate measurement of those on each cusp being 4 by 3 by 2 mm. Along the line of closure of the tricuspid cusps was a row of noncontinuous, shallow ulcers measuring up to 8 mm. in diameter. Their bases were yellow and firm, suggesting calcification. The pulmonary valve was normal. None of the valves showed any evidence of disease preceding the bacterial endocarditis.

The aorta showed a moderate degree of atherosclerosis, with focal ulceration in the abdominal portion. In the right common and external iliac veins were small mural thrombi that appeared organized. These lesions were brownish-gray nodules measuring 4 mm. in diameter and did not appreciably narrow the lumens.

The spleen was moderately enlarged, weighing 500 gm. The capsular surface was smooth, glistening and purple except at one point situated at the junction of the diaphragmatic and gastric surfaces. Here was a depression measuring 1.0 by 0.8 by 0.5 cm. The tissues directly beneath this area for a depth of 5 mm. were firm and grayish yellow. Elsewhere, the cut surfaces were deep reddish purple and were studded with numerous bulging, translucent, semigelatinous nodules measuring up to 1 mm. in diameter.

The kidneys were of normal size, their combined weight being 300 gm. The capsules stripped with ease and revealed pale-gray, smooth surfaces on which were numerous linear and punctate red areas suggesting hemor-

rhages. Each cortex measured 5 mm. in thickness. On the pale-gray cut surfaces were punctate red areas.

The prostatic urethra was wide, measuring 1 cm. in diameter. It was walled by firm, fibrous prostatic tissue, which averaged 1 cm. in thickness and from which several gray nodules bulged above the cut surface. The seminal vesicles were slightly pale and thicker than usual.

The rectum contained a polyp measuring 1.0 by 0.8 by 0.5 cm.

Microscopic examination of the various tissues substantiated the anatomic findings. A section of the left ventricle taken through the yellow areas, revealed scattered, small areas in which the muscle fibers had lost their nuclei and had developed a granular cytoplasm. In some places a small number of muscle fibers had disappeared, only stroma with dilated capillaries remaining.

The bacterial endocarditis appeared to be of longest duration on the mitral valve. A section of the cusp showed it to be thickened by fibrous tissue, infiltrated with lymphocytes, plasma cells and macrophages, and to have capillaries coursing through breaks in the elastica. On the auricular surface of the valve were several clumps of gram-positive diplococci partially covered with fibrin

FIGURE 2.

*Photograph of the mitral vegetation in Case 1. Gram-positive cocci are present in clusters and suggestive chains (Gram-Weigert stain,  $\times 1350$ ).*

(Fig. 2). In the underlying endocardium was young granulation tissue heavily infiltrated with neutrophilic leukocytes.

The section of the aortic valve showed a more recent and more acute lesion. Here was an ulceration extending through the entire thickness of the leaflet. At the margin of the ulcer were clumps of bacteria and organizing fibrin infiltrated with polymorphonuclear leukocytes. The fibrous thickening and vascularity seen in the mitral valve were absent.

The Malpighian corpuscles of the spleen contained a moderate amount of amyloid. Beneath the depression in the splenic capsule, the parenchyma was replaced by fibrous tissue infiltrated with a moderate number of lymphocytes, plasma cells and macrophages.

In the kidney, numerous glomerular spaces and adjacent tubular lumens contained fresh and old blood. There was no definite glomerular necrosis. The basement membranes of many glomerular tufts were thickened by a slight to moderate amount of amyloid.

The prostatic tissue showed moderate fibrosis but no evidence of active inflammation. However, the mucosa of the seminal vesicles was thickened by granulation tissue and contained small numbers of gram-positive diplococci. Within the lumens of the vesicles were polymor-

phon clear leukocytes, lymphocytes and macrophages

The rectal polyp was a typical benign polyp. At its base was an infiltration of a small number of neutrophilic leukocytes.

The final diagnoses were subacute bacterial endocarditis, with extensive involvement of the mitral valve and slight involvement of the aortic and tricuspid valves, focal myocardial infarction, amyloidosis of the spleen, kidney and adrenal glands, healed infarct of the spleen, polyp of the rectum, old thrombophlebitis of the right common and external iliac veins, chronic seminal vesiculitis.

**CASE 2.** A 60-year-old, Russian Jewish printer was admitted to the hospital on July 12, 1939, with the chief complaint of difficulty in breathing, cough and intermittent pain in the chest increasing in severity during the preceding 4 weeks.

The past history was noncontributory.

In 1933, the patient first noted slight difficulty in breathing. Despite gradually increasing shortness of breath he was able to continue work until March, 1936, when he was admitted to the hospital with the chief complaints of difficulty in breathing when prone and of swelling of the legs.

Physical examination at that time revealed a well developed and well nourished man experiencing slight dyspnea. Moist rales were heard in the posterior, basal portion of each lung field. The heart was enlarged to the left, and the heart sounds were of fair quality, without murmurs. The pulse was irregular, with a rate of 120. The blood pressure was 160/110. The lower border of the liver was palpated three fingerbreadths below the right costal margin in the right midclavicular line. Varicosities and marked pitting edema were present in both lower legs.

Laboratory data revealed a hemoglobin level of 85 per cent (Sahli), and a white-cell count of 5800. The blood nonprotein nitrogen level was 27 mg per 100 cc. A blood Kahn reaction was negative. The urine was essentially normal. An electrocardiogram disclosed a ventricular rate of 85 and a QRS interval of 0.08 second,  $T_1$  was upright,  $T_2$  diphasic, and  $T_3$  flat, and the axis was normal. These findings were interpreted as indicating auricular fibrillation and myocardial damage.

The patient responded favorably to the administration of digitalis and was discharged on the 13th hospital day. Thereafter, he continued to take digitalis and was able to work intermittently for about 2 years. During 1938, he found it necessary to restrict his activity because of progressive difficulty in breathing on exertion. About 3 months before his final admission to the hospital, he developed moderate difficulty in breathing when at rest, a moist, unproductive cough, with associated pain in the chest, intermittent swelling of the ankles and episodes characterized by hot and chilly sensations. For the week preceding entry, he felt especially "choked up."

Physical examination in July, 1939, revealed the patient to be orthopneic, cyanotic and in obvious respiratory distress, with a moist cough. The tongue was dry, and the teeth moderately carious. The pupils were irregular and slightly dilated, and reacted sluggishly to light. Ophthalmoscopic examination disclosed moderate tortuosity of the arteries and moderate venous congestion, with moderate arteriovenous nicking. There were bilateral pulsations at the root of the neck and moderate distention of the cervical veins. There were dullness, diminished breath sounds and rales at the bases of both lungs, and there was an area of dullness, with loud bronchial breathing and bronchophony, at the angle of the left scapula. The point

of maximum cardiac impulse was at the left anterior axillary line in the 6th interspace, and the area of supra-cardiac dullness was increased in width. At the apex was a systolic thrill. A harsh, high pitched systolic murmur was heard over the entire precordium and was loudest at the apex. There was a soft, blowing diastolic murmur at the mitral area and the right sternal angle, but it was loudest over the sternum. The pulmonary second sound was louder than the aortic. The cardiac rhythm was totally irregular, and the ventricular rate averaged 70. The blood pressure was 170/65. There was a right inguinal hernia. The area of hepatic dullness extended three fingerbreadths below the costal margin in the right midclavicular line. Rectal examination showed external hemorrhoids. There was moderate pitting edema of the lower legs. A vascular tumor was present on the right palm. The radial and brachial arteries were moderately thickened and tortuous. The reflexes were physiologic.

Laboratory data showed the urine to be acid and to have a specific gravity varying from 1.011 to 1.020. Albumin and sugar were constantly absent. The urinary sediment contained 0 to 5 leukocytes and 0 to 3 granular casts per high power field. Hematologic studies showed a red cell count of 4,100,000, a hemoglobin of 83 per cent (Sahli) and white-cell counts varying from 31,600 to 57,000. Differential leukocyte counts averaged 88 per cent neutrophils, 8 per cent monocytes and 4 per cent lymphocytes. A blood Hinton reaction was negative. Nonprotein nitrogen levels of 86 and 89 mg per 100 cc were obtained. Roentgenograms of the chest showed a general enlargement of the heart without increase in the size of the aorta, congestive changes in both lower lobes and a pneumonic process in both midlung fields. An electrocardiogram taken the day after admission disclosed auricular fibrillation, a ventricular rate of 95, a QRS interval of 0.07 second,  $T_1$ ,  $T_2$  and  $T_4$  diphasic with low origin,  $T_3$  inverted with low origin, and a normal axis. The interpretation was auricular fibrillation and myocardial damage. On the same day, the vital capacity was 2.2 liters, the circulation time 23 seconds, and the venous pressure in the left arm 7 cm of water. A sputum culture grew a streptococcus with alpha hemolysis and *Staphylococcus aureus*. Seven daily blood cultures grew enterococci.

The patient's temperature rose to 101.1°F on the 2nd day, dropped to normal for 4 days, and terminally rose to 100.1°F. The pulse rate averaged 88, except for a rise to 120 during the last 2 days. Similarly, the respiratory rate averaged 30, with a terminal rise to 52. Treatment consisted in venesection, with removal of 600 cc of blood, digitalis, Mercupurine, aminophyllin and sulfapyridine. During the 2nd day, the patient developed a Cheyne-Stokes type of respiration, which continued intermittently thereafter. The cardiac sounds varied from a harsh, high pitched, apical systolic murmur and a soft, blowing diastolic murmur to low pitched, booming systolic and low pitched diastolic murmurs. On several occasions, the diastolic murmurs were inaudible, and once a soft aortic diastolic murmur was heard. On the 3rd hospital day, petechiae were noted in the right conjunctiva and over the right upper arm. The patient failed to improve, developing on the 7th day a persistent Cheyne-Stokes type of respiration, increasing temperature and pulse rate, and rales. He died on the following day, July 20.

**Autopsy.** An autopsy was performed 12 hours post mortem. Only the important findings are given.

The heart was increased in size, weighing 500 gm. The myocardium of each ventricle was hypertrophied, the left measuring 2 cm in thickness, and the right 8 mm. The coronary arteries showed a mild degree of athero-

sclerosis but no appreciable degree of narrowing of their lumens.

The mitral valve evinced a well-established rheumatic stenosis, the valve orifice being narrowed to a diameter of approximately 1 cm. On the auricular surfaces of the fused mitral cusps was a bulky vegetation. This was firmly attached to the endocardium and measured 2.3 cm. in width and 6 mm. in height. The remaining valves were normal.

In the cecum was a smooth-surfaced polyp measuring 8 mm. in diameter. Adjacent to this was an area of superficial ulceration with a dark, brownish-green base, measuring 4 cm. in greatest extent. The rectum showed some hemorrhoids.

The kidneys were reduced in size, their combined weight being 190 gm. The capsules stripped with ease, and the parenchymal surface was smooth except for an occasional linear scar 3 mm. or less in depth. On section, the cortex averaged 5 mm. in thickness and was pinkish red, with no evident hemorrhages.

Microscopic examination of the various tissues substantiated the anatomic findings. A section of the left ventricle revealed small foci in which the muscle fibers had disappeared; only stroma with dilated capillaries and scattered pigment-laden macrophages remained.

A section of the mitral valve disclosed an ulceration extending through the entire substance of the leaflet. The hiatus was filled by a vegetation composed of partially organized, old fibrin, erythrocytes, leukocytes and gram-

FIGURE 3.

Photograph of the mitral vegetation in Case 2. Gram-positive cocci are present in clusters (Gram-Weigert stain,  $\times 1350$ ).

positive cocci in pairs, short chains and clusters (Fig. 3). Beneath the ulcerated surfaces was young granulation tissue. In the substance of the leaflet remote from the ulceration were foci of necrosis and infiltration of moderate numbers of polymorphonuclear leukocytes.

In the gastrointestinal tract were two lesions, one in the rectum, and one in the cecum. The section of the rectal lesion disclosed hemorrhoids of moderate size and also an acute inflammatory process in the mucosa. The lesion in the cecum was characterized by infarctlike necrosis, with ulceration and infiltration and a moderate number of neutrophils and many diplococci and bacilli. Cocci in pairs and short chains were the predominating organisms in the cecal wall.

The final diagnoses were: subacute bacterial endocarditis involving the mitral valve; old rheumatic heart disease, with mitral stenosis; myocardial hypertrophy; focal myocardial infarction; pulmonary congestion and edema; polyp and focal acute ulceration of the cecum; hemorrhoids.

## BACTERIOLOGY

The organism of Case 1 (Strain A) was obtained in pure culture from four ante-mortem cultures, in conjunction with a *Str. viridans* from an extracted tooth, in pure culture from the heart's blood at autopsy, and in conjunction with a *Staph. albus* from the vegetation. The organism of Case 2 (Strain O) closely resembled that of Case 1. This strain was obtained in pure culture from six ante-mortem blood cultures and from another in conjunction with a *Staph. albus*. The post-mortem blood culture was negative. Cultures of the vegetation and an unorganized mural thrombus yielded the organism in pure culture.

On smear, the organisms are gram-positive, lanceolate diplococci, often appearing encapsulated, and arranged singly and in short chains. They grow well in broth, producing an even turbidity. On the surface of a blood-agar plate (20 per cent defibrinated sheep blood), they form discrete, small, grayish-white convex colonies, which produce a very faint zone of alpha hemolysis that is best seen after a colony is scraped aside. The organisms grow readily on the surface of 40 per cent bile agar and are insoluble in bile. They produce acid fermentation of dextrose, lactose, galactose, maltose, trehalose, salicin, sorbitol and mannitol, and split esculin. They do not ferment sucrose, arabinose, raffinose or inulin. The pH of dextrose broth is lowered from 7.0 to 4.3. Acid and a slight clot are formed in litmus milk. The two strains differ somewhat in their resistance to heat: Strain A resists a temperature of 60°C. for thirty minutes, whereas Strain O resists that temperature for ten minutes. Extracts of the organisms were tested for precipitin reactions with serums of Lancefield's Groups A to H streptococci, inclusive, and gave reactions with Group D anti-serums. These two strains were found not to correspond with the few known serologic types within this group.

## DISCUSSION

The term "enterococcus" is best used to denote a group of related organisms whose normal habitat is the intestinal tract. The enterococcus is described as a gram-positive, lanceolate diplococcus occurring in short chains.<sup>29, 42-47</sup> It is often somewhat pleomorphic and sometimes appears encapsulated. On the surface of blood agar, it grows well as a round, convex, lenticular, sharply contoured colony producing a slight amount of alpha hemolysis. It also grows well in broth or on agar containing 10 per cent, 20 per cent or 40 per cent bile, and is insoluble in bile. The organism is hardy, requiring infrequent transplanting, and

most strains resist a temperature of 60°C. for thirty minutes. Its biochemical activities include the formation of acid and a soft clot in litmus or methylene blue milk and the reduction of the pH of dextrose broth from 7.5 to 4.2. Acid without gas is produced in dextrose, lactose, sucrose, trehalose, salicin, mannitol and sorbitol, and inulin and raffinose are not fermented. Esculin is split. Antigenically, this group comprises Group D of Lancefield's classification.<sup>37, 41, 46, 47</sup>

Attempts at subdivision of the group on the basis of cultural and biochemical characteristics have resulted in considerable confusion. The American and English authors, exemplified by Sherman,<sup>46</sup> subdivide the enterococcus group into four closely related species, *Str. faecalis*, *Str. liquefaciens*, *Str. zymogenes* and *Str. durans*, of which the first is the type form. The more recent German authors, exemplified by Gundel,<sup>48</sup> divide the enterococci into Types A and B, of which Type B corresponds to the typical enterococcus and Type A exhibits less vigorous cultural and biochemical activities and less pathogenicity for mice than Type B. The development by Lancefield<sup>41</sup> of a practicable method of grouping streptococci on the basis of antigenic structure has already shown that many of the various species of enterococci belong to Group D.<sup>47</sup>

Comparison of the characteristics of the organisms recovered from these 2 cases with those of the type organism showed a striking similarity. In the tests used, Strain A reproduced the type reaction except for its failure to ferment sucrose. Similarly, Strain O differed from the type organism only in its failure to ferment sucrose and in its heat resistance. Despite these aberrations, it seems evident on the basis of cultural, biochemical and antigenic properties that these two organisms are enterococci.

Comment should also be made concerning the possible sources of entry of the enterococcus into the blood stream in these 2 cases. In Case 1, autopsy revealed two possible sources, the infected polyp of the colon and the seminal vesicles. The inflammatory lesion in the polyp was not extensive and undoubtedly originated at a later date than the endocarditis. On the other hand, the seminal vesicles evinced a long-standing inflammatory process and contained organisms morphologically similar to the enterococcus. These observations, together with the clinical history of the development of the endocarditis subsequent to the prostatectomy, imply but do not prove that the seminal vesiculitis was the portal of entry of the enterococcus. In Case 2, there were in the cecum and rectum moderately acute ulcerations heavily infiltrated with bacteria morphologically similar

to enterococci. Although these ulcerations might constitute the portal of entry of the organism, the acuteness of the lesions probably indicates that they were of more recent origin than the endocarditis.

Two other observations deserve mention. In each case, throughout the myocardium, were focal areas in which the muscle fibers had disappeared, only the stroma remaining. Such lesions are consistent with those produced by arterial occlusion. Although no occlusions of the coronary arteries were demonstrated, it is reasonable to assume that some of the smaller branches of the arteries were obstructed, possibly by emboli.

The other and more unusual complication of bacterial endocarditis was amyloidosis. Deposits of amyloid were found in the spleen, adrenal gland and kidney in Case 1. An explanation of its occurrence here might lie in the long duration of the endocarditis.

#### SUMMARY

Two cases of subacute bacterial endocarditis caused by an enterococcus are presented.

In Case 1, the symptoms of endocarditis appeared following a prostatectomy. The patient died seven months later. Necropsy showed typical vegetations involving the mitral, aortic and tricuspid valves, focal myocardial infarction, evidence of seminal vesiculitis of long duration and the unusual finding of amyloidosis. The organism (Strain A) was recovered from four ante-mortem blood cultures and an extracted tooth, and from the heart's blood and the vegetations at autopsy. There was no demonstrable underlying cardiac disease. The portal of entry may have been the infected seminal vesicles.

In Case 2, the symptoms of endocarditis appeared in a patient who had cardiac decompensation, which had progressed slowly throughout a six-year period. The duration of the endocarditis was probably about three months. Necropsy evinced old rheumatic heart disease, with involvement of the mitral valve, typical vegetations on that valve and focal myocardial infarction. Although fairly acute ulcerations of the rectum and sigmoid were found, these probably were of too recent occurrence to have been the portal of entry. The organism (Strain O) was recovered from seven ante-mortem blood cultures and from the vegetations and an unorganized mural thrombus at autopsy.

The characteristics of these organisms are those of an enterococcus, with the exceptions of the failure of both strains to ferment sucrose and the diminution of the heat resistance of Strain O. Both

strains are members of Group D (enterococcus) of Lancefield's classification of streptococci.

We are greatly indebted to Dr. A. R. Kimpton for permission to report Case 1 and to Dr. R. C. Lancefield for grouping and attempting to type the organisms.

# LEFT INGUINAL HERNIA WITH ACUTE MECKEL'S DIVERTICULITIS AND PERITONITIS

## Report of a Case

ROLI LIU, MD,\* AND SAMUEL T LADD, MD\*

PORTSMOUTH, NEW HAMPSHIRE

WHEN acute inflammation of Meckel's diverticulum is encountered at operation, it is usually recognized by the surgeon. We wish to report a case in which Meckel's diverticulitis complicated a strangulated left inguinal hernia. The diagnosis was not apparent until the patient had left the hospital and a considerable amount of detective effort had been expended.

## CASE REPORT

A 75 year-old, Irish-born, retired machinist was admitted to the Portsmouth Hospital on February 12, 1941. It was impossible to obtain an accurate detailed history from him because of mental confusion. The first symptom was generalized abdominal pain which began 2 weeks before admission. There had been some retching at the onset, but no vomiting. The patient had not noted any distention of the abdomen, nor did he describe the abdominal pain as crampy. During the 2 weeks before admission, he felt a steady soreness across the abdomen, and was unable to eat. The bowels moved without cathartics about once in three days. The first bowel movement was on the day of admission. There was no blood or mucus in the stools.

For the previous 2 years, the patient had noted gradually developing symptoms of prostatism. His urinary stream had become smaller, there was increasing difficulty in starting the urine, and he had nocturia of two to five times. At no time had he seen blood or pus in the urine. The patient had noted some dyspnea on exertion during the preceding 6 months, but no edema or paroxysmal nocturnal dyspnea. He had some orthopnea and used two pillows at night. The family and marital histories were noncontributory. The patient had used alcohol quite freely until 2 years before admission when he had stopped suddenly at the direction of his physician.

Physical examination showed a well developed and well nourished man with respirations of 30 and signs of dehydration. His pulse was completely irregular, with a radial pulse deficit of 15 beats. There were many coarse rales throughout the lungs, but no area of consolidation was found. The abdomen was soft and not distended, it was tender throughout, the maximum tenderness being over a mass in the left groin. This mass was firm and rounded, measured 4 cm in diameter, and was not reducible. It lay just above the center of Poupart's ligament. The blood pressure was 130/70. There were 4 or 5 white blood cells per high power field in the urine, but no albumin or sugar. The white-cell count was 29,000, with 89 per cent polymorphonuclear leukocytes. The temperature was 102.7° orally.

Four cat units of Digifolin were given intramuscularly, an intravenous injection of 10 per cent glucose in physiological saline was begun, and the operation on the mass in the left lower quadrant was undertaken with local

anesthesia. The preoperative diagnosis was strangulated inguinal hernia with a question of Richter's hernia.

The peritoneum was entered at a point above the hernia, and the sac opened from above. The neck was very narrow and consisted of a thick fibrous band. There was free seropurulent fluid in the abdominal cavity, with large flakes of fibrin. The loops of sigmoid and small intestine were bound together with fine adhesions. The posterior wall of the sac was composed of a 4 cm long, acutely inflamed tip of what appeared to be an appendix and its mesentery (Fig 1). The organ was visualized 4

FIGURE 1 Drawing of Operative Findings

A—cut edge of hernial sac, B—acutely inflamed tip of Meckel's diverticulum, C—cut edge of neck

cm above the tip, in the medial direction, and this portion seemed to lie entirely in the retroperitoneal area. Further exposure was not possible without extension of the incision.

In view of the patient's general condition, the simplest procedure was adopted: the inflamed tip was amputated, and the sac removed with it en masse. When the peritoneum was closed, it was necessary to overlap the edges somewhat so as not to incorporate the stump in the suture line.

The hernia was repaired with catgut, the second method of Halsted being used. The cord was left in its bed, the cremaster muscle was imbricated beneath the conjoined tendon and the conjoined tendon beneath the lower leaf of external oblique muscle, with the leaves of the

\*Surgeon Portsmouth Hospital

external oblique muscle overlapped. A drain was left in the lower angle of the wound. The report of Dr. H. N. Kingsford on the specimen was as follows:

The specimen consists of a sac, open at one end. It reveals a projection into its lumen measuring 4 by 1 cm. Sections show a peritoneal covering, subperitoneal tissue and two smooth-muscle layers, with a marked purulent exudate on the lumen edge of the section; there is absolutely no evidence of mucosa. This could be a Meckel's diverticulum or an appendix.

The convalescence was complicated by bronchopneumonia on the 2nd postoperative day; this was controlled by sulfathiazole. On the same day, the patient developed acute urinary retention, which necessitated an in-lying catheter. He was digitalized by the 3rd day, and from then on ran a regular pulse. The gastrointestinal tract revealed its functional integrity soon after operation by the passage of flatus, which continued to occur without abdominal discomfort. Sepsis developed in the wound, but 5 weeks after operation there was only a small sinus and no evidence that the hernia was recurring. The patient had recovered sufficiently 2 weeks after operation to undergo a transurethral resection for benign prostatic hypertrophy.

With the available evidence, it seemed that we had been dealing with an acute appendicitis and peritonitis in a left inguinal hernia. However, a barium enema done postoperatively showed the cecum in the right lower quadrant, with the appendix well outlined for a length of 10 cm. It was freely movable and showed no evidence of attachment to the site of the hernial sac. Previous to prostatectomy, a cystogram gave no indication of a bladder diverticulum. A gastrointestinal series six weeks after operation showed a loop of small bowel, about 30 cm. above the ileocecal valve, close to the anterior abdominal wall in the left

lower quadrant and apparently attached in this position (Fig. 2).

In the last analysis, it seems that the diagnosis was acute Meckel's diverticulitis in a left in-

FIGURE 2. Tracing of X-ray Plate Six Hours after a Barium Meal.

A—terminal ileum; B—point of fixation to site of hernial sac; C—cecum; D—line of abdominal wall.

inguinal hernia, with perforation and peritonitis, and not acute appendicitis, as we suspected at first.

## IRRADIATION IN THE TREATMENT OF CANCER OF THE BREAST\*

FREDERICK W. O'BRIEN, M.D.,† AND EUGENE McDONALD, M.D.‡

BOSTON

A DISCUSSION of the place of irradiation in the treatment of mammary cancer naturally divides itself into an attempt to evaluate the usefulness of the procedure in primary operable cases, as the sole therapeutic measure; as a preoperative procedure; as a postoperative routine; in the control of local recurrences and distant metastases; and in cases with frankly inoperable tumors.

The radiation method is based on the object of treatment, — namely, cure or palliation, — the physical setup — namely, adequate amounts of radium and roentgen-ray apparatus of accepted potential — and the experience of the radiologist. Because of the nature of this presentation, a detailed statistical analysis is not attempted.

*Irradiation Alone in Operable Cases*

Irradiation as the sole therapeutic measure is justifiable in cases, otherwise operable, in which the patient is a poor surgical risk, in the borderline operable patient and in specially organized clinics.

Since 1922, Keynes<sup>1</sup> has treated 390 selected cases of operable cancer of the breast with buried radium needles. He does not recommend their use in very advanced stages of breast cancer, cases with demonstrable distant metastases, avascular ulcerated tumors or very stout patients, since a great deal of fat in the breast and axilla makes accurate placing of the needles difficult. He considers all other cases suitable, and believes that patients in the very earliest stage of the disease are eminently suitable for radium treatment. He shows a five-year survival rate of 65.9 per cent, and he states that it is certain that many of the patients included in his Class I cases (with disease apparently confined to the breast) should really appear in Class II, that is, among those with metastatic involvement of the axillary glands. This fact suggests that if a correction for this error could be made, the statistical result in Class I would be very much better than it actually appears to be. Keynes sometimes removes the breast by diathermy. It must be remembered that his radium attack is a highly individualized surgical procedure.

We are not aware that anyone has systematically treated primary operable breast cancer with x-rays alone, except when for some reason surgical intervention has been contraindicated, and even

these cases do not run into numbers comparable with those of Keynes.

We do not believe, other things being equal, that irradiation to the exclusion of surgery should be employed in that group of patients with mammary cancers who, when operated on radically, give a five-year cure rate (alive without disease) of 70 per cent or better, as reported by Simmons and his associates.<sup>2</sup> It may be argued that this is a rigidly selected group, but that is as it should be. From our experience, it seems the part of wisdom to drop the term "operable breast cancer" and use the designation "curable cancer." The surgeon who thinks in terms of curable cancer is very much less likely to intervene in a case that is technically operable but in which operation would shorten the patient's life.

The extent of the disease, here as elsewhere, has come to be recognized as the most vital single factor influencing cure. Once the disease has extended to the axilla, the five-year cure rate by surgery drops to about 30 per cent. Less emphasis is placed on the grading of malignant tumors than formerly, for it has been shown that, regardless of the grade, if the tumor is localized and removed in its entirety, the cure rate is not affected. The grade of malignancy has, however, a prognostic value. Tumors of high malignancy are commoner in the younger age groups and are likelier to have already metastasized. These cases, for the most part, prevent a perfect surgical cure rate.

*Preoperative Irradiation*

The foregoing suggests the advisability of preoperative x-ray or radium therapy, not to supplant surgery but to complement it. Much of the criticism of preoperative irradiation has been justified. We do not believe that an inoperable cancer is made operable in the sense of curability by irradiation, but we do believe that the attempt should be made to immobilize tumors of high malignancy by judicious preoperative irradiation in an attempt to improve the cure rate of this group. And this can be done without prejudice to rather prompt surgical intervention.

The objections commonly raised against preoperative irradiation are that delay in operating creates a mental and physical hazard for the patient, and that adequate irradiation produces fibrosis, and makes the operation more difficult and the skin less likely to heal. Furthermore, if the

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1941.

†Chief, Tumor Clinic, Boston City Hospital.

‡Resident in radiology, Boston City Hospital.

tumor disappears under irradiation, the patient may be falsely misled into not returning for surgery; and, finally, there is no evidence to prove that preoperative irradiation is of benefit.

The last objection will always remain imposing and difficult to refute while surgeons hold out steadfastly against trial of the method. If patients are seen privately or in a tumor clinic and assured that the irradiation is in preparation for surgical excision later, no mental hazard need exist; the physical hazard already exists. If the disease has already extended to the axilla and beyond at the time of the first examination, it is difficult to reason that immediate irradiation will stimulate the spread of the disease rather than immobilize what is already there. There is no scientific evidence that irradiation stimulates tumor growth; on the contrary, there is abundant animal and human evidence that it halts neoplastic growth.

The method of administering preoperative irradiation, both the total dosage and the chronologic spacing of the unit dose, is of the greatest moment. The work of Adair and his associates<sup>3</sup> is frequently quoted in disparagement of preoperative irradiation. We agree that if one were to follow literally the method employed by Adair, one would have to expect the untoward results described by him. But it should be recalled that he intentionally used large doses of intensive radiation to obtain data on the cancerocidal effects of x-rays on the tumor in the breast and axillary nodes.

We do not believe that radiation in amounts sufficient to sterilize the tumor is either desirable or necessary after massive doses of x-radiation. Melnick and Bachem,<sup>4</sup> working with transplantable rat tumors, observed necrosis of tumor cells, hyperemia, cellular infiltration, granulation-tissue proliferation, fibrosis and blood-vessel changes, whereas after fractional and protracted methods of irradiation, only the most radiosensitive cells were destroyed by necrosis, the remaining resistant cells being transformed into tumor giant cells that degenerated not by necrosis but by calcium deposit, with no apparent effect in adjacent normal tissues. Melnick<sup>5</sup> repeated the experiments, using radon implants, with results parallel to those of the earlier study. In view of the experimental findings in animal tumors, Halley and Melnick<sup>6</sup> now prescribe preoperative irradiation extending over four or five weeks and followed by amputation within two to four weeks. A shorter preoperative course fails to obtain optimum tumor damage. The mutationlike effects, which they believe may be the most significant mechanism, require four to five weeks. Surgery done within two or three weeks of the end of irradiation has

the advantage of dealing with a tissue in which viable tumor cells have been decreased to a numerical minimum, with slight damage to the tumor bed. Delay of surgical interference beyond four weeks, according to Halley and Melnick, makes regrowth of the tumor probable. Optimum spacing of the radiation dose may well be the crux of the entire problem, as indicated in the work of Spear and Glücksmann.<sup>7</sup>

### *Postoperative Irradiation*

Routine postoperative irradiation has been abandoned in some clinics because of apparently paradoxical results, and carried on in others in the belief that the question is still *sub judice*. We are convinced that if postoperative irradiation is to be given in its commonly accepted sense of "prophylactic," many more fields of irradiation should be utilized than is the prevailing custom, as suggested by Lenz et al.<sup>8</sup> It is not sufficient to treat the affected chest wall, axilla and supraclavicular chain of lymphatics; one must treat the mediastinum and parasternal nodes, as well as the lymphatics of the opposite breast, over a protracted period.

We do not believe, however, that postoperative irradiation is necessary in those patients in whom the disease was localized in the breast by diagnostic roentgen-ray, operative and pathological examinations, with the exception of Grade III tumors, which are presumed to metastasize early. Roentgen-ray castration may be of value.

On the other hand, we are of the opinion that postoperative irradiation is definitely a useful therapeutic measure in patients whose disease appeared localized in the breast clinically but on pathological examination was found to have extended to the axillary nodes. In one series examined by us, 39 per cent of patients so classified lived over five years without demonstrable disease.

By far the largest group referred to our clinic for postoperative irradiation is made up of patients in whom the operation was frankly inadequate or of doubtful completeness. Irradiation of this group is usually only palliative, and is given with the idea of growth restraint and in the hope that if the remaining cancer cells are implanted elsewhere they may be less viable. Sometimes, physicians are critical of irradiation because it does not compensate in some miraculous way for lack of surgical judgment. Indeed, the radiation therapist has been accused of venality<sup>9</sup> when he treats these cases, whereas his confrere is pardoned for having operated on them. In our series of 50 consecutive cases of this type, 29 patients had surgery only and lived on the average nine months, whereas 21 who had surgery and irradiation lived

on the average over three years. Not a single patient in the first group lived five years, but in the latter group 5 lived for more than five years.

In 1940, a monograph<sup>10</sup> covering the treatment of cancer of the breast quoted, in censure of post-operative irradiation, statistics from a paper that appeared in 1935 based on cases operated on and irradiated from 1910 to 1929—a period when radiation therapy had hardly reached its adolescence. Many clinics during this time were treating patients with apparatus of diagnostic potential only. We believe that statistical data founded on radiation methods abandoned for more than a decade should be presented merely for what they are worth.

It should be plain that end results bear a direct relation to the criteria of operability, the extent of the disease, the degree of malignancy, the pathological interpretation, the kind of operation done, the skill of the operator and the use of any supplemental measure, such as radiation.

It is one thing to compare surgical end results in cases free of axillary nodes with similar cases that have had radiation added; it is another matter when axillary nodes or other complications are present. It is necessary to know how many patients had surgery only in the presence of skin ulceration, cutaneous nodules, supraclavicular nodes, distant metastases, secondary radical procedures, inflammatory carcinoma and lactating breasts; how many had surgery and irradiation, and when irradiation was given in relation to the operation. Much of the criticism leveled at radiation therapy is vitiated by failure to apply the principle that only like things are comparable.

#### *Irradiation for Local Recurrences and Distant Metastases*

Local recurrence in the skin or scar, when the nodules are discrete and few in number, may be excised surgically or treated by surface or interstitial radium or intensive x-radiation with a well localized field. If the nodules are multiple and contiguous, surgical removal is not usually advisable because of the loss of skin entailed thereby. In this situation, high voltage x-rays or radium when available in sufficient quantity is preferable.

The appearance of secondary nodules in the scar or skin of the breast area usually means that the extirpation of the mammary gland was not wide enough. Hicken<sup>11</sup> has shown by mammographic studies that the lactiferous ducts spread over the entire anterolateral wall of the chest. Examining breasts supposed to have been completely

excised by "mastectomy procedures" after injection of the ducts with a solution of methylene blue, he did not find a single case in which the mammary tissue had been removed in its entirety. In 94 per cent of the cases, the dye escaped in the subareolar zone, indicating that some of the breast had been left attached to the reflected skin flaps.

In an earlier study of 255 cases of breast cancer, one of us (F W O B<sup>12</sup>) found recurrence in the skin or scar in 21 per cent of the cases. The appearance time of the local recurrence in this group seemed directly related to the completeness of the surgical excision and the extent of the disease at the time of operation, rather than to the kind of tumor.

Distant metastases, on the other hand, involve other factors than completeness of operation and extent of the disease. They occur when, according to the rules of the game, they should not. In such cases, the kind of tumor and its method of spread by the lymphatics or vertebral veins seem of significance. The estrogenic theory of multiple foci of origin must also be considered when one discusses what seems to be a metastasis but what in reality may be one of several primary foci.

Often enough, metastases that are presumed to be postoperative were present at the time of surgical intervention. It is safe to assume that bone metastasis demonstrable by x-ray study ten days after operation has been present for a much longer period. In the records of more than 50 per cent of one series examined by us, there was no evidence of preoperative diagnostic x-ray examination. Roentgenologic study of the chest, spine and pelvis should be made before operation, as White<sup>13</sup> counsels, without regard to the smallness of the primary tumor, lack of nodes or suggestive symptoms. When this procedure is employed, many cancers clinically localized prove to be diffuse and inoperable.

Distant metastases may be controlled for long periods by appropriate gamma radiation or high voltage x-rays. In suspected bone metastasis, irradiation should be promptly directed to the site of pain irrespective of negative diagnostic x-ray examination. The entire vertebral column may be riddled with tumor, without demonstrable roentgenologic findings. Any orthopedic appliance used in the presence of collapse of the vertebral bodies or fracture of the long bones that will preclude irradiation, since new bone formation often enough follows its application, should be interdicted. Occasionally, generalized skeletal

metastases have disappeared completely following irradiation of the ovaries.

Pleural effusion sometimes resolves after relatively small doses of medium-voltage x-ray therapy, and the progress of lung metastasis is halted by fibrosis deliberately produced by the employment of supervoltage radiation. Such therapy is palliative, to be sure, but it is comparable in some measure with therapeusis in certain other chronic but fatal maladies common to the field of internal medicine.

#### *Irradiation of Inoperable Tumors*

The inoperable cases are cheerfully passed on to the radiation therapist. Although such cases are hopeless as a group, enough palliative benefit ensues to justify acceptance of such patients when they are not in extremis. Ulcerating breasts frequently heal, axillary and supraclavicular nodes regress, but secondary deposits appear in the skeleton or other organs. Care should be exercised that these patients have proper medical follow-up. A judicious use of sedatives, antianemic remedies and relatively small doses of radiation help a few to live in comparative comfort for five years or longer.

\* \* \*

In conclusion, we do not claim that irradiation is in competition with surgery. We wholeheart-

edly subscribe to the dictum that any surgeon who does less than a radical operation in curable breast cancer is not giving his patient even a sporting chance for recovery. Likewise, we believe that the surgeon who studiously condemns irradiation on statistical data derived from cases treated just after the turn of the century, when the limits of surgical curability were ill defined and radiation therapy was still undeveloped, denies to his patient a therapeutic aid to longer life.

## MEDICAL PROGRESS

### MEDICAL ASPECTS OF OBSTETRICS

JUDSON A. SMITH, M.D.\*

BOSTON

OF THE medical complications of pregnancy, the most important are those conditions characterized by hypertension and albuminuria and often loosely grouped under the old-fashioned and misleading designation "toxemias of pregnancy." In 1940, the American Committee on Maternal Welfare adopted a classification of these toxemias that now seems to be gaining acceptance by obstetric clinics throughout the country. It was presented with a detailed explanation in a recent paper by Mussey and Hunt<sup>1</sup> and is given below in a slightly condensed form.

#### GROUP A Diseases not peculiar to pregnancy

##### I Hypertensive disease (hypertensive cardiovascular disease)

- a Benign (essential)
- b Malignant

##### II Renal Disease

- a Chronic vascular nephritis or nephrosclerosis
- b Glomerulonephritis
- c Nephrosis
- d Other renal disease (such as pyelonephritis)

#### GROUP B Disease dependent on, or peculiar to, pregnancy

##### I Pre-eclampsia

- a Mild
- b Severe

##### II Eclampsia

- a Convulsive
- b Nonconvulsive (that is, with coma and post mortem findings typical of eclampsia)

This classification is entirely logical in theory, if one accepts the underlying assumption that there is a specific hypertensive disease peculiar to pregnancy. Group A is composed of cardiovascular and renal diseases that occur independently of pregnancy and whose association with pregnancy is therefore a matter of chance. Group B consists of a single disease, which is in some way caused by pregnancy and which is referred to as pre-eclampsia or eclampsia according to the severity of the symptoms. The persistent belief that eclampsia is a pathologic entity has rested mainly on three facts: it occurs in women who have never

previously shown evidence of cardiovascular or renal disease, it not infrequently results in complete recovery, leaving no demonstrable evidence of impairment of the cardiovascular system or kidney, and its typical picture has not been observed apart from pregnancy.

The actual classification of individual cases according to the above scheme, at least during pregnancy, is often difficult or impossible, largely because there is no readily available diagnostic test by which pre-eclampsia can be recognized. We are forced to rely on two empirical facts: eclampsia rarely, if ever, occurs before the sixth lunar month, and pre-existing vascular or renal disease is usually definitely aggravated by the pregnancy before the sixth month. The twenty-fourth week, therefore, is arbitrarily taken as a dividing line. Hypertension appearing before that time is regarded as *prima facie* evidence of a pre-existing disease independent of the pregnancy, hypertension appearing after the twenty-fourth week in a woman who has no history of vascular or renal disease is regarded as *prima facie* evidence of pre-eclampsia. These criteria, of course, are not perfectly satisfactory. If, for example, a patient with pre-existing mild vascular hypertension becomes worse later in pregnancy, it is difficult to decide whether the original disease is aggravated or she is beginning to develop superimposed pre-eclampsia. Furthermore, in cases of mild hypertension appearing soon after the twenty-fourth week and remaining mild, it is usually impossible to determine whether the condition is delayed aggravation of a pre-existing vascular or renal disease or a mild subacute pre-eclampsia. As a practical rule in the management of these cases, however, it is always safer to regard acute exacerbations of hypertension or albuminuria as indicative of pre-eclampsia.

The distribution of these conditions, when classified as above, is shown in Table 1, which is taken from a recent study by Irving<sup>2</sup> of 1182 consecutive cases of hypertension and albuminuria in pregnancy.

During the past year, Smith, Smith and Schiller<sup>3</sup> have made an extremely interesting and valuable contribution to the study of the etiology of pre-eclampsia. They measured the levels of pregnanediol, estradiol, estrone and estriol and the es-

Reprints of articles in this series are not available for distribution but the articles will be published in book form. The current volume is *Medical Progress Annual 1940* (Springfield III no. 5 Charles C Thomas Company 1941 \$4.00).

trogenic potency after hydrogenation in the urines of 22 patients with pre-eclampsia and eclampsia and of 15 normal women during the last tri-

TABLE 1. *Diagnosis in 1182 Consecutive Cases of Hypertension and Albuminuria in Pregnancy.*

DIAGNOSIS	NO. OF CASES	PER CENT
Essential hypertension .....	68	5.8
Chronic renal disease .....	13	1.1
Pre-eclampsia, mild .....	889	75.0
Pre-eclampsia, severe (including 13 cases of eclampsia) .....	212	18.1

mester. The results indicated that pre-eclampsia is associated with a progressive deficiency of progesterin, which results in a greater and more rapid destruction of estrogens. They consider this derangement of estrogen metabolism to be due to disturbed placental function, which, they point out, might result from numerous mechanical or organic interferences with placental blood supply. Their ideas of the relation between the changed estrogen metabolism and symptoms of pre-eclampsia are best expressed in their own words:

We are convinced that the significant finding, so far as the clinical manifestations of pre-eclampsia and eclampsia are concerned, is the sudden, rapid destruction of estrogens. The menstrual phenomenon has also been found to be accompanied by the same evidence for rapid destruction of the estrogens following estrogen and progesterin withdrawal. Furthermore, there is a striking similarity between the local changes in the premenstrual endometrium and the generalized disturbances so characteristic of pre-eclampsia and eclampsia. The menstrual discharge has been found to contain a potent toxin to the action of which we would attribute the local changes resulting in menstruation. The formation of this toxin appears to be closely allied to rapid destruction of the estrogens. By analogy, we would postulate that the same shift of steroid metabolism in pregnancy results in the formation, on a larger scale, of a similar toxin, possibly in the decidua. The albuminuria of pre-eclampsia might be ascribed to the effect of such a toxin acting on the kidney glomeruli, the hypertension to an actual Goldblatt phenomenon from renal arteriolar constriction due to the same toxin, and edema to an effect upon capillaries similar to that which takes place in the premenstrual endometrium.

Having arrived at these admittedly speculative conclusions, they tested them by treating a small series of patients with pre-eclampsia with daily injections of estrogen and progesterin. The resulting shift toward normal in both the clinical manifestations and the hormonal changes was considered sufficient to bear out their theory. The authors noted, however, that the difficulty and expense of giving adequate daily doses of these hormones, for the present at least, preclude their use as a practical therapeutic measure.

Some newer methods of studying renal function have revived interest in this aspect of the hypertensive complications of late pregnancy. The

phenolphthalein excretion, concentration test and urea clearance are usually normal in both essential hypertension and pre-eclampsia. When, however, the renal blood flow per unit of time and the filtration fraction are determined, certain deviations from normal appear.

By the filtration fraction is meant the proportion of plasma that is filtered through the walls of the glomerular capillaries into Bowman's capsule—that is, the ratio of the amount of the glomerular filtrate during a certain time to the amount of plasma that flowed through the kidneys during the same period. To determine the plasma flow, use is made of the fact that Diodrast, at low concentration in the plasma, has a renal-excretion ratio of very nearly 100 per cent. In other words, of all the Diodrast carried to the kidney by the renal artery, none escapes by the renal vein. Thus, measurement of the plasma level of Diodrast and of the amount excreted per minute permits calculation of the amount of plasma that has flowed through the kidneys. The volume of the glomerular filtrate can be measured simultaneously by determining the ratio of the quantity of inulin excreted each minute to the plasma level of inulin, since inulin is neither excreted nor absorbed by the cells of the tubules. The normal filtration ratio is about 0.20.

Corcoran and Page<sup>4</sup> have studied a series of late toxemias of pregnancy by these methods and report that there are three groups. In Group I, the plasma flow was diminished, and the filtration fraction was increased. These findings are consistent with constricted efferent arterioles and normal capillaries, and are characteristic of essential hypertension in the nonpregnant woman. The patients in this group presented the clinical picture of pre-existing or latent essential hypertension. In Group II, the filtration fraction was low, and the clinical picture was that of severe pre-eclampsia or eclampsia. Corcoran and Page suggest that a lowered filtration fraction is the physiologic manifestation of the swelling of the basement membrane of the glomerular capillaries, which is generally regarded as the characteristic renal lesion of pre-eclampsia and eclampsia. In Group III, the filtration fraction was normal, and the clinical manifestations were mild. The authors do not attempt to classify these cases but believe that many of them represent mild pre-eclampsia.

Chesley<sup>5</sup> has reported similar findings and has come to similar conclusions. He believes that the lowered filtration fraction indicates severe glomerular damage, and suggests that, if pre-eclampsia or eclampsia is a cause of subsequent hypertension, the patients with a marked lowering of the filtration fraction should show a high incidence of hypertension later. In his series of 10 cases, 4 pa-

tients were hypertensive—that is, they had blood pressures above 140 systolic, 90 diastolic—two years later. He also reports observations on 7 patients with normal blood pressure one to four years after severe pre-eclampsia or eclampsia. In several cases, there was a marked deficit in renal blood flow, and in 2 cases a marked lowering of the filtration fraction. Chesley suggests that in some of these cases, in spite of the absence of hypertension, there may be glomerular damage.

The frequency with which a so called "toxic" pregnancy is followed by essential hypertension or chronic cardiovascular disease has been repeatedly pointed out in the last few years. The most recent contribution of this sort is a statistical study by Peckham<sup>6</sup> of 500 such patients observed throughout pregnancy and subsequently followed from two to ten years. For inclusion in this group, it was required that the patient should have made a minimum of three visits to the clinic, at each of which the blood pressure and urine were normal. This resulted in the selection of a group of patients none of whom showed evidence of toxemia before the fourth lunar month. Of the entire group, 63 per cent were found to have chronic vascular damage. The series was divided first according to the month of onset of toxemia and then according to the time elapsed between the onset and delivery. It was found that the incidence of permanent damage was greater the earlier the onset and the longer the time between onset and delivery. Peckham believes the latter factor to be the more significant in prognosis and suggests that four weeks should be the maximum period of observation of the toxic patient, ignoring, apparently, the problem of the viability or nonviability of the fetus. A complete discussion of these statistics is impossible, but attention must be directed to one point concerning the apparent effect of long duration of the toxemia, namely, that the longer the time elapsed between the onset of toxic symptoms and delivery, the likelier it is that the clinical picture was the type to suggest latent pre-existing vascular disease rather than pre-eclampsia.

There has been no progress in the therapy of the toxemias of pregnancy. Goethals<sup>7</sup> last year discussed the treatment of eclampsia with veratrum viride, as reported by Bryant and Fleming.<sup>8</sup> If there have been any further reports of the use of this drug they have escaped my notice. Nicodemus<sup>9</sup> describes the treatment of 13 eclamptic patients with the oxygen tent; all recovered. Although this result is of no statistical significance, the idea seems, a priori, to be worthy of trial.

Numerous reports<sup>10-18</sup> have recently been published that add to the evidence of the effectiveness of Vitamin K in preventing hemorrhagic disease of the newborn. The ideal method of prophylaxis seems to be the parenteral adminis-

tration of Vitamin K to the mother at the onset of labor and to the infant immediately after birth. There can no longer be any excuse for neglecting this precaution. Javert and Macri<sup>19</sup> present some evidence suggesting that the daily ingestion of mineral oil leads to a deficiency of Vitamin K in pregnant women by preventing absorption.

There is nothing to be added to the chemotherapy of puerperal sepsis except the introduction of a new analogue of sulfanilamide, namely, sulfadiazine. Long,<sup>20</sup> who has made a preliminary report on this drug, finds that it is somewhat less rapidly absorbed from the gastrointestinal tract than sulfanilamide, sulfapyridine and sulfathiazole, and that it is somewhat less rapidly excreted than sulfanilamide or sulfapyridine, when renal function is normal. It is relatively easy to maintain an adequate concentration of the drug in the blood, and as a matter of fact, the blood level must be followed carefully to prevent unnecessarily high concentrations. It produces very little nausea and vomiting and appears to be less apt to cause drug fever and drug rash than sulfanilamide, sulfapyridine and sulfathiazole. Up to the time of his report, Long had observed no cases of renal injury. Its effectiveness in hemolytic streptococcus infections compares favorably with that of sulfanilamide. As yet, there has not been sufficient experience with sulfadiazine to make its evaluation possible.

Heckel<sup>21</sup> discusses the possibility that chemotherapy during pregnancy and the puerperium may injure the fetus in utero or the nursing infant. He considers injury to the nursing infant from sulfanilamide extremely unlikely. This drug is excreted in the milk in a concentration approximating that in the blood. A nursing infant consequently can get only a minute dose from its mother's milk. Babies nursed by mothers receiving 4 gm. a day showed only traces of the drug in the blood and behaved quite normally. Injury to the fetus is theoretically possible, since there is evidence that the concentration of sulfanilamide in the fetal blood is equal to that in the mother's within a few hours after administration. Heckel reports results in 13 women who were given chemotherapy at various stages of pregnancy and followed through delivery. Twelve of the infants were normal. One infant had a moderately severe anemia, for which no cause could be found. Heckel suggests that the anemia might have been due to the sulfanilamide administered to the mother. She had received daily doses (maximum, 30 gr.) to a total of about 750 gr. over a period of thirty seven days, terminating fifteen days before delivery. Whatever the chances of injury to the fetus may be, they are no greater, he believes, with large doses than with small ones.

Steiner and Lushbaugh<sup>22</sup> believe that they have

recognized a new obstetric disease. They report 8 cases of unexpected and rather sudden maternal death during labor or soon after delivery. Clinically, the symptoms were those of severe shock. In some cases, there was atony of the uterus and post-partum hemorrhage, but only after the appearance of shock. In some cases, there was acute pulmonary edema. The essential pathologic condition was found on microscopic examination to be widespread embolism of small pulmonary arteries, arterioles and capillaries by the particulate matter found in amniotic fluid and by meconium. They have duplicated the disease clinically and pathologically in rabbits and dogs by the intravenous injection of human amniotic fluid and meconium. Three of their cases were found at the Chicago Lying-in Hospital over a period of nine years, during which time there were 24,200 deliveries, an incidence of 1 in about 8000 deliveries.

Some recent discoveries in connection with intragroup transfusion reactions are of great interest to obstetricians. The subject of isoimmunization in relation to intragroup reactions has been completely presented in a progress report by Hooker.<sup>23</sup> The facts that are of interest to the obstetrician concern the atypical agglutinin, which has been named the Rh factor (because it occurs in the blood of the *Macacus rhesus* monkey) and which is present in the red cells of about 86 per cent of human bloods.<sup>24</sup> Persons who have this factor in their red cells are Rh+; the 14 per cent of persons who lack it are Rh-. Since the Rh factor is inherited according to the Mendelian law as a dominant,<sup>25</sup> the children of an Rh- mother and an Rh+ father will all be Rh+ if the father is homozygous with respect to this factor. If the father is heterozygous with respect to the Rh factor, half the children will be Rh+. The frequency of such marriages (Rh- wife, Rh+ husband), if due to chance alone, should obviously be about 12 in 100. There is now convincing evidence<sup>26, 27</sup> that sometimes when an Rh- woman is carrying an Rh+ fetus in her uterus, Rh antigen from the fetal blood gains access to the maternal blood and stimulates the production of antibodies; the maternal antibodies readily diffuse into the fetal circulation, destroying fetal red cells and producing the disease known as erythroblastosis foetalis. From these facts, it is apparent that if the mother of an erythroblastotic child is transfused with blood from her Rh+ husband or from any other Rh+ donor, there is grave danger of a reaction. A number of such reactions have been reported—some fatal.<sup>27</sup> It must be borne in mind that this is an intragroup reaction—ordinary direct cross-matching of bloods will not detect the incompatibility. It can be detected, however, by incubating a mixture of recipient's

serum and donor's cells at 37°C. for thirty minutes.<sup>28</sup> This precaution (incubation) in cross-matching, therefore, becomes imperative in the selection of donors for all pregnant and parous women. If incompatibility is found, it will be necessary to determine at once the Rh status of the woman. If she is Rh- and her blood contains anti-Rh antibodies, she can be safely transfused only from a donor in the correct blood group who is also Rh-. Since finding such a donor might take some time, maternity clinics should have lists of donors whose Rh status has been determined. It is well to remember, if one is in a hurry for an Rh- donor, that since the character of being Rh- is a recessive, a brother or sister of the Rh- patient is much likelier to be Rh- than a donor selected at random.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 28011

### PRESENTATION OF CASE

A sixty-three-year-old housewife, formerly a factory worker, was admitted to the hospital because of jaundice, malaise, nausea, vomiting, weakness and abdominal discomfort.

She had been in excellent health until four years before admission, when she began to have intermittent episodes of malaise, nausea and vomiting, chills, slight jaundice and frontal headaches, which lasted about two weeks and recurred at intervals varying from two weeks to six months. The earliest attacks were apparently precipitated by the eating of fatty foods, which had thenceforth been carefully avoided. During the attacks, the urine was dark, and the stools were frequently light colored. There was remission of jaundice between the episodes, with return to normal-appearing dejecta. The first few spells were accompanied by dull pains in the hips and back, but there were no such pains subsequently. In the few months preceding admission, the bouts of illness became severer and more frequent, and marked weakness began to appear. In the course of the four years, there was a loss of about 70 pounds in weight.

At no time in the illness was there hematemesis, melena or obvious fever. The patient denied any medication other than proprietary preparations of "bile salts" and "liver pills," prescribed by her physician.

The last episode started on an afternoon eleven days before entry, with abrupt onset of nausea and vomiting, followed by increasing malaise, weakness, jaundice and passage of dark urine. On the next day, the patient experienced shaking chills lasting for two or three hours; she did not feel feverish. In the following days, the chills recurred. Most of the stools were light colored, but some were green. There was progressive weakness, much severer than that on any previous occasion. Three or four days before entry, the abdomen became swollen and tender.

A brother of the patient had died of tuberculosis at the age of twenty-seven (when the patient was eighteen years old). The past history was otherwise of no interest. Until eight months

before entry, the patient had worked in a factory, putting linings in shoes. She knew of no exposure to chemicals or fumes. She denied the use of alcohol.

On admission, the patient appeared emaciated, quite uncomplaining and free of discomfort. There was moderate icterus of the skin and scleras. The chest was emphysematous, with rales and slight dullness at the pulmonary bases. The size of the heart was within normal limits; the heart sounds were slightly distant. The abdomen was moderately distended and tympanitic, with shifting dullness and a demonstrable fluid wave. There were moderate external hemorrhoids. The skin showed diffuse, slight edema.

The temperature was 100°F., the pulse 110, and the respirations 24. The blood pressure was 118 systolic, 70 diastolic.

Examination of the blood showed a red-cell count of 4,150,000 with 13.7 gm. hemoglobin, and a white-cell count of 10,600 with 88 per cent polymorphonuclears. The blood Hinton reaction was negative. The van den Bergh reaction was biphasic, and showed 4.6 mg. bilirubin per 100 cc. The blood cholesterol was 172 mg. per 100 cc. The phosphatase was 25.7 Bodansky units, and the phosphorus 2.8 mg. per 100 cc. The serum albumin was 2.7 gm. and the serum globulin 4.0 gm. per 100 cc. The prothrombin time was normal. The hematocrit was 39.3 per cent. The bromsulfalein test showed 50 per cent dye retention.

The urine was normal except for the finding of bile by the foam test. The stools were pasty and soft green, with a positive guaiac reaction.

A roentgenogram of the chest showed elevation of the right diaphragm, with haziness in the right costophrenic angle. There were several areas of calcification in the right lower-lung field and hilus. Fluoroscopy demonstrated limited motion of the right diaphragm, in the correct direction, and absence of fluid in the right costophrenic angle. The diaphragm appeared pushed up by the liver. A roentgenogram of the abdomen showed enlargement of both the liver and spleen. There was no evidence of dilatation of bowel loops. The Graham test was positive.

On the sixth hospital day, a peritoneoscopy was performed.

### DIFFERENTIAL DIAGNOSIS

DR. F. DENNETTE ADAMS: It seems unlikely that the chills reported were, in the strict sense of the word, real chills, for these do not last so long as two or three hours—nor do they often come more than twice daily. I should be inclined to interpret them as the chilly sensations that accompany rises of temperature.

Nothing is said about the size of the liver and spleen on palpation; enlargement of either or both could well have been overlooked because of unsatisfactory palpation due to abdominal distention. Before proceeding, we might learn from Dr. Lingley whether he believes that these organs were enlarged.

DR. JAMES R. LINGLEY: This is the film of the chest, showing the high right diaphragm with a shallow costophrenic angle. The lower hepatic border is not well visualized, but the liver is probably enlarged. The spleen, however, is not appreciably increased in size. The gall bladder is not visualized on any of the films, and the Graham test is therefore positive.

DR. ADAMS: I shall consider this problem first from the standpoint of jaundice. The causes of jaundice may be classified as hematogenous, obstructive and hepatogenous. Hematogenous jaundice, in this case, can be readily excluded. We are obviously not dealing with such disturbances as pernicious anemia, severe generalized sepsis and familial hematogenous jaundice. Stone in the common duct and cancer account for most cases of obstructive jaundice. If this patient had cancer of the head of the pancreas, lymph-node enlargement, which might occur in lymphoblastoma, or cancer of the biliary tract interfering with the flow of bile, the jaundice would have been progressive, not intermittent, and by this time would have been severer than the findings in this case indicate. Furthermore, the gall bladder would have been large and, even with the abdomen distended, might have been palpable. The duration of the illness was long for cancer. Stone in the common duct will be considered later.

Of the hepatogenous causes, one must consider some acute intrahepatic process such as catarrhal jaundice or toxic hepatitis, cirrhosis of the liver, diffuse neoplastic disease of the liver, such as lymphoma or carcinoma, and cholangitis with ascending infection into the liver. The duration was too long for any acute intrahepatic process, and diffuse neoplastic disease can be excluded by the same line of reasoning that I have applied to cancer involving the bile passages.

Of the various forms of cirrhosis, one need hardly consider that due to syphilis or cardiac disease, or pigment cirrhosis (hemachromatosis). There is nothing to point toward any of these.

Portal and biliary cirrhosis require further thought. The history is not suggestive of portal cirrhosis. There is no record of a previous acute liver ailment, nor is there any mention of alcoholism. The only suggestive points in favor of portal cirrhosis are the ascites and the laboratory

evidence of impaired liver function. Bouts of pain simulating gall-bladder colic are not infrequently encountered in portal cirrhosis, but on the other hand, jaundice is not usually a feature except in the terminal stages.

The history of recurrent episodes of pain, jaundice, fever and gastrointestinal disturbance is perfectly typical of biliary cirrhosis. It is also typical of common-duct stone with intermittent obstruction. But biliary cirrhosis rarely occurs except in the presence of long-standing biliary-tract disease.

The laboratory tests — especially the high blood phosphatase, the low serum protein and the diminished excretion of bromsulfalein — indicate an appreciable degree of liver impairment, more than one would expect with common-duct stone alone unless the jaundice were of greater degree. By x-ray examination, the liver appeared large; the spleen may have been slightly enlarged — added evidence in favor of liver disease.

Since it seems impossible to explain all the changes on the basis of common-duct stone, one is forced to the conclusion that cirrhosis existed; if so, it must have been of the biliary type. But the presence of biliary cirrhosis presupposes previously existing obstruction or infection, and these would most probably be the result of stone in the common duct. The most likely diagnosis, then, in my opinion, is chronic cholecystitis with stones, stone in the common duct, ascending biliary-tract infection secondary to obstruction, and biliary cirrhosis secondary to the ascending infection.

One other problem deserves brief consideration. Could there have been carcinoma of the liver in addition? Primary carcinoma of the liver is not uncommon in cirrhosis and is rarely seen without cirrhosis. It is not commonly diagnosed ante mortem. One can suspect its presence in cases of cirrhosis when a definite mass can be felt in the liver, when a localized bulge of the diaphragm is discovered roentgenologically, or when metastatic cancer is discovered elsewhere. There was no evidence of metastasis, and the only hint of cancer in this case might be obtained from the roentgenologist. Dr. Lingley, should you consider the elevation of the diaphragm general, or do you think there is a localized bulge?

DR. LINGLEY: I should consider it either an enlarged liver or an infectious process beneath the dome of the diaphragm producing elevation and limitation; no definite localized bulge is apparent.

DR. ADAMS: Then I shall not add a diagnosis of primary carcinoma of the liver.

DR. TRACY B. MALLORY: Does anyone want to ask any questions or give suggestions at this point?

**A PHYSICIAN:** It seems to me that we should give serious consideration to the possibility that this was carcinoma of the ampulla of Vater. That might explain the absence of pain and the itching, and waxing and waning frequently goes with it.

**DR. MALLORY:** The presence of a large amount of ascites with biliary cirrhosis would bother me a little bit.

**DR. ADAMS:** It bothered me. Ascites is, of course, not common in biliary cirrhosis except in the terminal stages. Barring portal cirrhosis, which I do not believe existed in this case, I should say that the ascites is much more suggestive of carcinoma, but the evidence in favor of common-duct stone and biliary cirrhosis outweighs the doubt introduced by the ascites. Except for the ascites, the picture is typical of common-duct stone.

**DR. WYMAN RICHARDSON:** If you will believe me, the patient did have ascites. I am sure of it.

**DR. ADAMS:** It is too late for me to go on the other side.

**DR. MALLORY:** Dr. Richardson, do you want to comment before or after we have heard the peritoneoscopic findings?

**DR. RICHARDSON:** I should like to read the note that I made before peritoneoscopy was done. I think that is the fairest way. "Because of the history, I believe that this patient has had recurring biliary infection, perhaps with stone and with secondary biliary cirrhosis. She may have had recurring cholangitis and recurring focal liver degeneration, followed by distortion and ascites (end stage of toxic hepatitis)." I am attempting to explain the ascites, but rather poorly. "In spite of weight loss, in addition to high phosphatase, I doubt malignant tumor. If present, it must be secondary to primary liver disease, such as cirrhosis; and I cannot make out that the patient has a primary cirrhosis. Advise peritoneoscopy."

**DR. MALLORY:** Dr. Benedict, will you tell your gross findings?

**DR. EDWARD B. BENEDICT:** I shall read my report: "Under local anesthesia, a 1-cm. incision was made in the midline just above the umbilicus, the peritoneal cavity inflated with air, and the Ruddock peritoneoscope introduced. Ten pints of slightly cloudy, straw-colored fluid was aspirated and sent to the laboratory. There were many adhesions between the edge of the liver and the abdominal wall. The liver did not appear enlarged. Multiple cystic implants were visible throughout the peritoneum—on the round ligament, on the wall of the bowel, on the brim of the pelvis and throughout the pelvis. There was also a cystic appearance to the surface of the liver, as if that also were involved in the process. The

uterus was quite freely movable when examined by vagina and by rectum by Dr. McGahey. There were cystic implants on the surface of the uterus and on the broad ligaments. The ovaries could not be brought into view. There was considerable hemorrhagic appearance to the metastatic disease of the anterior abdominal wall overlying the lower abdomen and pelvis. Biopsy specimens were obtained from implants in the pelvis and from an area of the anterior peritoneum overlying the liver."

**DR. MALLORY:** What was your impression at the end?

**DR. BENEDICT:** General carcinomatosis.

**DR. MALLORY:** Dr. Benedict's various biopsy specimens were examined histologically, and all of them showed tuberculosis.

**DR. RICHARDSON:** I shall read one further note, which I wrote after the peritoneoscopy: "I am not satisfied with the diagnosis of tuberculosis in this patient." I did not mean to say that I doubted the pathologist. I believed that the patient must have had tuberculosis, but that something else was present. I said: "If it is present, there must be another pathologic process. I believe that it is most probably tumor. There may also be cirrhosis of the liver." That is as far as I went.

**DR. MALLORY:** Do you want to make a further diagnosis, Dr. Adams?

**DR. ADAMS:** I am very grateful for Dr. Richardson's support. I fail to see how tuberculous peritonitis can explain the whole picture. Nor can I make any diagnosis other than the one I have already made, on the basis of the evidence provided by the protocol. How could the jaundice be explained by tuberculous peritonitis?

**DR. MALLORY:** I am in a prejudiced position. I cannot explain it, however.

**DR. RICHARDSON:** And we could not on the service.

**DR. MALLORY:** One might imagine large tuberculous nodes pressing on the common duct, but I have not seen that in a case of tuberculous peritonitis, and I think it would be unlikely.

#### CLINICAL DIAGNOSES

Recurring biliary infection.

Cholelithiasis, with secondary biliary cirrhosis?

#### DR. ADAMS'S DIAGNOSES

Chronic cholecystitis, with cholelithiasis.

Stone in the common duct.

Ascending biliary-tract infection (cholangitis), with infectious (biliary) cirrhosis of the liver.

## ANATOMICAL DIAGNOSES

Tuberculous peritonitis.  
 Miliary tuberculosis.  
 Pulmonary tuberculosis, healed.  
 Tuberculosis of hilar glands, healed.  
 Cholecystitis, chronic.  
 Cholelithiasis, choledocholithiasis.  
 Nephrosclerosis, moderate.  
 Operative scar, peritoneoscopy.

## PATHOLOGICAL DISCUSSION

DR. MALLORY: This patient continued to pursue a downhill course, and at autopsy we found, besides the tuberculous peritonitis, a gall bladder full of stones, and immensely dilated common bile and hepatic ducts. Twenty-eight stones were counted in the common duct. Gallstones unquestionably were the cause of the jaundice. There was a moderate degree of secondary cholangitis; it was on the border line of chronicity at which one begins to speak of biliary cirrhosis. There were also miliary tubercles in the liver and a great many in the spleen, which was consequently considerably enlarged, and there were scattered tubercles in the lungs. The primary cause of death was the generalized tuberculous infection.

## CASE 28012

## PRESENTATION OF CASE

A twenty-nine-year-old housewife was admitted complaining of headache and diminished vision in both eyes.

She was perfectly well until three years before admission, when her first child was born. Although the delivery was normal, she vomited during the whole course of her pregnancy. At that time, she believed that her blood pressure was normal. After delivery, she had periodic attacks of vomiting, which six months later were accompanied by pains in both sides of the face, over the eyes and at the back of the neck. Vomiting began regularly a week before her period and lasted until the menses began. She was relieved during the time of flow, but vomited again for the following week. The pain lasted twelve hours, whereas the vomiting lasted a week. One year before entry, the patient again became pregnant. Her physician said that her blood pressure was high. During this pregnancy, she vomited constantly, had dizzy spells, and in the seventh month, began having throbbing pain over her entire head, with throbbing in the ears, especially after eating. She miscarried during the seventh month, but the emesis continued, and she lost weight steadily afterward. One month following the miscarriage, the blood pressure was 170 systolic, 120 diastolic, and the

urine showed a heavy trace of albumin. During the next few months, headaches and vomiting continued, and the blood pressure ranged from 200 to 210 systolic, 130 to 140 diastolic. The patient returned to work, but gradually became weak and dyspneic. The menses ceased four months before entry. During these four months, she vomited at least once daily, the vomitus consisting of brown foul-smelling fluid but no blood. During the last three months, she occasionally blew clots of blood from her nose, but had no frank epistaxis; this partially relieved the headache. She also felt more drowsy during this period, objected to having people around her, and finally answered questions in a peculiar manner. One month before admission, she suddenly noticed decreased peripheral vision and could not read well, mainly because of blurring. Three weeks before entry, she was seen in the Out Patient Department. The blood pressure was 210 systolic, 118 diastolic. The urine showed a specific gravity of 1.004, 2 white blood cells and a few epithelial cells per high-power field, and a slight trace of albumin. The red-cell count was 2,900,000 with 50 per cent hemoglobin, and the white-cell count was 12,500. The patient was to return later for study. Two weeks later, constant slight epistaxis began. Three days before entry, muscular twitchings were noted. One day later, the ankles began to swell. She had lost 34 pounds in weight during the previous year.

The past and family histories were noncontributory.

Physical examination showed a well-developed but emaciated, dehydrated young woman, with a pasty, pale appearance, who lay quietly in bed. She was stuporous, answered questions with difficulty and at times did not respond at all. The pupils were normal. The fundi showed tortuous vessels with arteriovenous nicking. The disks were somewhat blurred. Exudate and a small hemorrhage were seen near the macula in the left eye. The tongue was dry and brown, and the mouth covered with sordes. The breath was strongly ammoniacal. Examination of the lungs was negative except for a few coarse rales at the bases. The left border of the heart was 10 cm. to the left of the midline. The apical rate was 140; there were occasional extrasystoles and a marked pulsus alternans, only the stronger beats reaching the wrist. A precordial friction rub was heard. The veins were full but collapsed at the level of the auricle. The liver edge was palpable 3 cm. below the costal margin, and the upper edge was at the sixth interspace. The deep reflexes were sluggish. Occasional muscular twitchings were noted in the extremities.

The temperature was 98°F, the pulse 120, and the respirations 10. The blood pressure was 160 systolic, 90 diastolic.

Examination of the urine showed a specific gravity ranging from 1.004 to 1.014, a large trace of albumin, and 0 red cells, 20 to 30 white cells and many squamous epithelial casts per high-power field. The blood showed a red cell count of 2,600,000 with 50 per cent hemoglobin, and a white cell count of 9200 with 91 per cent polymorphonuclears. The nonprotein nitrogen of the serum was 310 mg per 100 cc, the chlorides 82 milliequiv. per liter, the carbon dioxide combining power 37.2 vol per cent, and the protein 7.6 gm per 100 cc. A lumbar puncture showed normal findings.

The patient rapidly failed and died one day after admission.

#### DIFFERENTIAL DIAGNOSIS

DR ASHTON GRAYBIEL: First of all, I shall briefly discuss and attempt to evaluate certain features of this history that are either of interest in themselves or contribute to the making of a diagnosis.

It would be of help to establish the duration of the illness. The first symptoms, nausea and vomiting, occurred three years before death, during the entire course of the patient's first pregnancy. I am not sure why she vomited—perhaps because of toxemia or neurosis. I believe it is unusual for a patient to have vomiting due to toxemia throughout pregnancy and yet deliver a normal baby—abortion or miscarriage is the rule.

We do not know how long the patient had hypertension before death. She thought that her blood pressure had been normal during her first pregnancy, but she was probably asked the question directly and was not quite sure of the answer. The first definite knowledge of hypertension was near the beginning of the second pregnancy, one year before death. The patient was twenty-eight years of age at that time, which is very young for one to have developed essential hypertension with its sequelae. This immediately arouses the suspicion that the primary disease was in the kidneys. If kidney disease is related entirely or almost entirely to pregnancy, it tends to disappear, and the patient becomes well, once the uterus is emptied. In this case, vomiting continued, and the high blood pressure persisted following miscarriage.

The history states that "during the last three months, she occasionally blew clots of blood from her nose . . . ; this partially relieved the headache." It seems impossible that the loss of such small amounts of blood would be important in this respect.

During the last three months of life, the patient became drowsy and mentally deranged; in the light of later developments, this was obviously due to uremic poisoning. Later, she developed twitchings, whose immediate cause was thought to be disturbances in calcium metabolism.

The urinary findings observed three weeks before death are especially interesting in that there was only a slight trace of albumin and 2 white blood cells and no red blood cells per high power field.

I might point out that the swelling of the ankles noticed three days before death need not necessarily be explained on the basis of heart failure. This swelling may have been due to capillary damage as a result of the high degree of toxemia. The rales heard over the lung bases might be explained on the same basis.

The changes in the retinas and retinal vessels deserve especial note. A small amount of exudate was observed in one eye, the vessels were tortuous, and only one small hemorrhage was seen. In the malignant phase of essential hypertension, the retinal changes are much more marked, and this fact is a strong argument against this diagnosis.

The history states that "there were occasional extrasystoles and a marked pulsus alternans, only the stronger beats reaching the wrist." I have never observed this phenomenon, but in turning to the literature I found that Lewis\* says that it can occur. Nevertheless, I doubt the accuracy of the observation in this case. An electrocardiogram might have shown that the weaker beats were regularly occurring extrasystoles. Without this record, there is some chance for confusion, especially when it is remembered that, in pulsus alternans, the interval between the small and large pulses is shorter than that between the large and small.

A precordial friction rub is not uncommonly heard in uremia. It is due to fibrinous pericarditis and is a grave prognostic sign.

The nonprotein nitrogen was 310 mg per 100 cc, which is an extremely high value. This is final proof of the existence of marked kidney failure. Whenever the nonprotein nitrogen attains the level of 200 mg. or more, it may be safely concluded that the functional capacity of the kidneys is about nil. The low value for chlorides represents chloride depletion as a result of vomiting. The carbon dioxide combining power of 37.2 vol. per cent is proof of acidosis.

If this case is considered in a straightforward fashion, the facts suggest that the patient had developed glomerulonephritis some time in the

\*Lewis, T. *The Mechanism and Graphic Registration of the Heart Beat*. Third edition. 529 pp. London: Shaw and Sons Ltd. 1915. P. 434.

past, and that, at the time of pregnancy, symptoms and signs of kidney failure appeared. During the second pregnancy, she became very toxic. The blood pressure was markedly elevated, probably as a result of the kidney insufficiency. She developed uremia despite the fact that the uterus was emptied, and I think she died with uremic poisoning. There is nothing that would lead one to suspect that the patient had had essential hypertension in the past and died in the malignant stage of the disease. Apparently the heart was somewhat enlarged, but there is no clearcut evidence of congestive failure; the edema over the shins and the rales in the lungs could be satisfactorily explained on the basis of uremic poisoning. The coronary vessels were probably in quite good condition. The microscopic appearance of the myocardium may prove to be abnormal simply because of toxic changes. A curious type of myocarditis associated with uremic poisoning has been described.

DR. PAUL D. WHITE: I quite agree that there probably was not a true *pulsus alternans* in this case but that a bigeminal rhythm due to extrasystoles accounted for the failure of alternate pulse waves to reach the wrist. I have examined a good many cases of *pulsus alternans* and have not found any in which the pulse has actually failed to reach the wrist. However, it does appear that there was marked cardiac enlargement, which is a background for true alternation of the pulse.

Should one expect to find anything wrong with the cerebral blood vessels? It is possible that the patient had edema of the brain or, as so often happens, small hemorrhages. I do not know whether the brain was examined, but I should think that either of these possibilities might be mentioned.

DR. FRANCIS R. DIEUAIDE: I should like to raise the question whether, in spite of the age of this patient, renal damage on a vascular basis should not be considered. It is true she was young, but certain findings suggest the possibility. One is the nature of the urinary findings. If one takes them seriously, the low specific gravity, with the small amount of albumin and relatively insignificant sediment content, seems to me to point toward that type of chronic renal condition rather than chronic nephritis on a previous glomerular basis.

DR. GRAYBIEL: I remain unconvinced that the patient had essential hypertension, which had developed into the malignant stage. Under such conditions, she might well have shown even more abnormality in the urine than she did. If she had nephrosclerosis of fairly short duration, she might well have had many red cells and a great deal of

albumin in the urine. Sometimes, in chronic glomerulonephritis, the urinary findings are not very remarkable. I think that the inconspicuous eye-ground findings are also somewhat against the diagnosis of a severe grade of malignant hypertension. I still favor the diagnosis of a chronic glomerulonephritis, aggravated particularly by the pregnancy.

#### CLINICAL DIAGNOSES

Glomerulonephritis.

Uremia.

Hypertensive heart disease, with congestive failure.

#### DR. GRAYBIEL'S DIAGNOSES

Chronic glomerulonephritis.

Uremia.

Arterial hypertension.

Cardiac hypertrophy, slight to marked.

Uremic pericarditis.

#### ANATOMICAL DIAGNOSES

Chronic glomerulonephritis.

Cardiac hypertrophy, left ventricular.

Pericarditis, acute fibrinous, uremic.

(Uremia.)

#### PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: Very often, at post-mortem, when the kidneys on gross examination are so shrunk that it may be impossible to make a definite diagnosis, even the pathologist has great difficulty in making a decision. In the ordinary type of malignant vascular nephritis in a woman of twenty-nine, the kidneys would not decrease in size to the degree of a chronic glomerulonephritis. The kidneys in a patient with malignant vascular nephritis rarely shrink to less than two thirds the normal weight, in contrast to chronic glomerulonephritis, in which the kidney weight may be less than one fourth the normal.

This patient had chronic glomerulonephritis. The kidneys weighed 90 gm., and microscopically there were innumerable hyalinized glomeruli, with crescent formation, which is characteristic of chronic glomerulonephritis. There was a uremic pericarditis of the so-called "bread-and-butter" type, thick fibrin strands producing interadherence between the two layers of pericardium, and 50 cc. of straw-colored fluid. The heart was hypertrophied and weighed 400 gm. The hypertrophy was for the most part left ventricular and was undoubtedly secondary to the nephritis. There was nothing of significance in the other organs, and no sign of heart failure.

ENROLLMENT FORM FOR PROCUREMENT AND  
ASSIGNMENT SERVICE FOR PHYSICIANS

Dr. Sam F. Seeley, Executive Officer  
Procurement and Assignment Service  
New Social Security Building  
4th and C Streets, S.W.  
Washington, D. C.

Dear Dr. Seeley:

Please enroll my name as a physician ready to give service in the Army or Navy of the United States when needed in the current emergency. I will apply to the Corps Area commander in my area when notified by your office of the desirability of such application.

Signed\_\_\_\_\_

1. Give your name in full, including your full middle name:

2. The date of your birth:

3. The place of your birth:

4. Are you married or single?

5. Have you any children? If so, how many?

6. Do you believe yourself to be physically fit and able to meet the physical standards for the Army and Navy Medical Corps?

7. Have you filled out previously the questionnaire sent to all physicians by the American Medical Association?

8. When and where were you graduated in medicine?

9. In what state are you licensed to practice?

10. Do you now hold any position which might be considered essential to the maintenance of the civilian medical needs of your community? If so, state these appointments:

11. Have you previously applied for entry into the Army or Navy Medical Service? If so, state when, where and with what result (if rejected, state why).

## A CALL TO SERVICE

WAR has already greatly increased the need of the United States Army and Navy for medical officers, and as pointed out in an editorial in the December 18 issue of the *Journal*, appreciable numbers of medically trained men are required for service in other governmental agencies. Because of this, a meeting of the Procurement and Assignment Service, in conjunction with the medical preparedness committees of the American Medical Association, American Dental Association and American Veterinary Medical Association, was held in Chicago on December 18, to devise means for making available to the Army and Navy the names of all physicians, dentists and veterinarians who are willing to enroll immediately in governmental service. Although this information was

requested on the questionnaires sent out by the American Medical Association, the forms had no official status and were filled out at a time when the United States was not an active participant in the war. Furthermore, the amendment of the Selective Service Act to include all men under forty five years of age places many more physicians in the group of those who may be called for active service.

For the convenience of physicians who are willing to serve the Nation in the event of need, an enrollment form that was carried in the December 27 issue of the *Journal of the American Medical Association* is reproduced on the opposite page. On receipt of the forms by the Procurement and Assignment Service, each enrollee will be classified according to information already available in the national roster of physicians at the headquarters of the American Medical Association, and so far as possible, assignment will be made to the type of service for which he is best suited. It is obvious that adequate medical service to civilian communities, public-health agencies and industrial plants must be continued, and committees are already being established in corps areas, states and counties to ensure the proper distribution of physicians.

To wage war successfully, all groups must be prepared to make great sacrifices, and it is to be expected that the medical profession—trained in a code of selfless devotion to duty—will accept this call to service with the cheerful readiness that it has shown in the past

## BLOOD PROCUREMENT SERVICE

At the request of the Surgeons General of the United States Army and Navy, the American Red Cross and the Division of Medical Sciences of the National Research Council have co-operatively organized a blood procurement service for the purpose of supplying the medical departments of the Army and Navy with human blood plasma. Thus far, six procurement centers are in operation in eastern United States, and five others are in the process of organization. During the past year, sufficient blood has been obtained in Boston to fill

the needs of a pilot plant for the production of crystalline human albumin under the direction of Prof. E. J. Cohn, of the Department of Physical Chemistry, Harvard Medical School.

Now that war has been declared, the activities of the Boston Procurement Center must be tremendously increased to supply blood for conversion to dried plasma, and the prewar quota of 17,000 donors within the next five or six months is but a fraction of what will eventually be needed. Quarters have been established at 691 Boylston Street, a personnel has been trained, and 100 donors are being bled daily. The organization of the procurement center and the technics used are those adopted as standard for the country by the American Red Cross and the National Research Council, and the final product meets all the requirements of the National Institute of Health.

Great care is exercised in selecting the donors. They must be twenty-one to sixty years of age and in good health. They are acceptable only if they have a hemoglobin level of 80 per cent or higher and a systolic blood pressure lying between 100 and 200 and if they have not been bled within eight weeks. Mature minors may be accepted as donors with the written permission of a parent or legal guardian. Five hundred cubic centimeters of blood is taken from donors of average size, and the facts that the repeat donor percentage is high and that reports from employers indicate that mass bleedings at manufacturing plants have not decreased the workers' efficiency indicate that this amount has caused no ill effects.

This meritorious project deserves the wholehearted support of the medical profession, because it not only provides an essential means of saving human life but also affords every citizen an opportunity to make a worth-while contribution to the war effort. A ready response will augment the growing morale of the armed forces and do much to crystallize *esprit de corps* among civilians.

## MEDICAL EPONYM

### LUDWIG'S ANGINA

Wilhelm Friedrich von Ludwig (1790-1865) communicated his vivid description of "a variety

of inflammation of the neck which has recently been of frequent occurrence in this community" to the *Medicinisches Correspondenz-Blatt des württembergischen ärztlichen Vereins* (6: 21, 1836). A portion of the translation follows:

After a series of prodromal symptoms . . . there develops a firm swelling . . . usually in the cellular tissue surrounding the submaxillary gland. This . . . swelling spreads around the neck under the jaw . . . with marked lateral bulging. . . The tongue lies on a floor of . . . indurated bright-red tissue which feels like a hard, calloused ring along the inner border of the jaw inside the mouth. . . Ability to open the mouth is restricted and painful . . . speech is difficult . . . thick and gurgling. . . The skin, . . . in the early stages at least, is very slightly reddened if at all and is normal in texture; . . . later, soft red spots may appear . . . but no pus is ever formed. . . The symptoms of the subsequent rapid course are those of a putrid-typhoid process, and in four to five days, the tenth to twelfth from the onset of the illness, coma develops and death occurs with indications of respiratory paralysis.

R. W. B.

## MASSACHUSETTS MEDICAL SOCIETY

### COMMITTEE ON MATERNAL WELFARE

At the annual meeting of the Council of the Massachusetts Medical Society, held in May, 1941, a resolution to establish a committee on maternal welfare was passed. This resolution also empowered the President to name a committee whose membership should represent geographically the various sections of the State. The resolution was presented to the Council by members of the Section of Obstetrics and Gynecology because it was believed that, to carry on some phases of the work that had come before the section, a committee having delegated authority should be established. In accordance with this vote, the President appointed the following committee: Dr. Judson A. Smith, chairman, Boston; Dr. Thomas Almy, Fall River; Dr. Robert L. DeNormandie, Boston; Dr. M. Luise Diez, Boston; Dr. Christopher J. Duncan, Brookline; Dr. M. Fletcher Eades, Boston; Dr. Arthur F. G. Edgelow, Springfield; Dr. Rachel L. Hardwick, Boston; Dr. Joseph W. O'Connor, Worcester; Dr. Louis E. Phaneuf, Boston; Dr. George M. Shipton, Pittsfield; Dr. Warren R. Sisson, Boston; Dr. Richard M. Smith, Boston; Dr. Raymond S. Titus, Boston; and Dr. Richard J. Williams, Lynn. This committee has met and organized. The chairman, Dr. Judson A. Smith, was appointed by the President; the secretary, Dr. Titus, was elected by the committee.

In October, 1941, a meeting of the Executive Committee of the Section of Obstetrics and Gynecology

cology was held in Boston. It was the opinion of this committee that, since a committee on maternal welfare had been appointed, much of the work that the section had carried on should be relinquished to this committee, an official body of the Massachusetts Medical Society. Hence, the study on maternal welfare, which the Section of Obstetrics and Gynecology has conducted for the past five years, was turned over to the Committee on Maternal Welfare, as of December 31, 1941 and from now on, all work of this type, except that pertaining to arrangements for the annual meeting of the section, will be handled by this committee. The case histories that have been appearing in the *Journal* will continue, at least for the time being. In next week's issue of the *Journal*, a résumé of the study of maternal deaths during 1940 will appear.

#### MEDICAL SOCIAL SERVICE FOR THE HANDICAPPED CHILD\*

In these weekly broadcasts, sponsored by the medical profession you have heard from a great many physicians and public health authorities about the advances in medical knowledge. You have been given information important to every intelligent person, concerning the common diseases and their care.

As one long associated with the medical profession in service to patients I want to share with you some of my experiences as a medical social worker in a large medical institution where specialization in the many branches of medicine is to be found. Medical social service is established in most of our big hospitals and clinics. You may well ask what social service has to do with medical institutions. Any of you who have had experience with sickness yourselves or have had illness in the family know how disturbing sickness can be. Often, it is more than pain and distress. It upsets our regular way of life. It may mean that we must stop work, lose time at school or give up some special pleasure we had anticipated. These experiences are common to us all.

Fortunately not all of us have had the more serious diseases which are well known in our great hospitals and to the medical profession, sicknesses that mean that the patient may not be able to work again or that he must learn to live with a chronic disease that may have to have treatment over a long time. I have in mind a girl with diabetes, who must learn to control her diet habits and who may have to take insulin every day for many years. I think of the boy with infantile paralysis, who must have many months and possibly years of muscle training—possibly operations. He may have to learn to walk with braces. And I think of the child who has lost his precious eyesight.

Does all this bring sad pictures to your minds? If it does I wish you could know as I do many of the courageous cheerful men, women and children who have been able to face such sicknesses, who have done their part in getting well or, if not well, in still finding that life can be very much worth while.

As one such courageous patient said: "It's not what is gone, but what is left for me that counts now. Sometimes sickness and the way the patient takes it are the means of opportunities for a fuller life. It is a curious fact that it may take such experience to awaken us to what we may be. I am thinking of a fine, active young boy, a leader in sports who was stricken with infantile paralysis at fourteen years of age just as he was about to enter high school. For a time, the future seemed very bleak to him. But under skillful medical care and through his own determination to do his exercises regularly he was able after two years to get about with crutches and braces. But this improvement in the condition of his body was only part of this boy's problem. What about his "rager active mind"? What about his education? What can he ever do to support himself? He is not the kind of person who wants to be dependent on others. Herein the medical social worker could help the patient and the doctor. For the doctor, too, wants the patient to be restored to useful living. Accordingly arrangements were made for his education first in a specialized school for handicapped children where the floors are not slippery for crutches and braces and ramps are used instead of stairs. He has made a good record through seven years and with the help of a generous person he is now in college preparing for journalism.

The other day a boy came from a distant town to one of the clinics for examination of his ear. His mother reported that he had been considered dull in school and had to repeat his grade. His parents considered him a "bright enough child but thought he did not pay attention when he was spoken to. Finally, one of his teachers suggested that he was not hearing well and advised the parents to have him examined. At the clinic his hearing was carefully tested and it was found that he heard nothing with the right ear and that the left was defective. For this boy several things can be done. A letter to the teacher advises that he sit in the front row in the right side of the room, so that his left ear can be used as much as possible. Then lip reading instruction can be started so that he may learn to depend on his eyes more than his defective ears for understanding what people say. Periodic examination of his left ear will be made. Let us hope that he has no further loss of hearing. But it will be well to have some aptitude tests to see in what line he has special ability. He should be guided into the kind of work he is fitted for by nature so that his handicap may be minimized.

Perhaps many of you have your own family doctor. If you do you know how much more he does for you than make a diagnosis and order medicine. He is an adviser and friend who helps you face the problems that sickness brings. But in our great clinics where patients go who have no family doctors or our great hospitals to which many people are sent for care it has been found necessary to have a person who can spare the busy doctor's time and give patients counsel in their difficulties and practical help in working out their problem.

Massachusetts like many other states is much concerned about helping people who are in trouble—whether it is support for those who are destitute, protection for neglected children, education of the handicapped, blind or deaf, medical care for crippled children or for the patients with tuberculous cancer and those with mental diseases, rehabilitation of those who can be trained for special work, protection of workers from the hazards in industry, compensation for those injured at work. Then too, through generous citizens there are many privately

\*A Green Girls to Health broadcast given through Station WAAB by Miss Ida M. Cannon on Saturday, November 22, and sponsored by the Public Education Committee of the Massachusetts Medical Society and the Massachusetts Department of Public Health.

supported resources to supplement the public agencies, resources for help in difficult family problems, foster homes for children who cannot be in their own homes, hospitals, clinics, centers for recreation and agencies for helping those who come from across the seas to seek new homes in our land. The medical social worker must be very familiar with all these resources. Her knowledge and skill in helping people to help themselves is called on every day as physicians in our great medical institutions ask her assistance for patients under their care. But if she is a well-trained social worker, she wants every citizen to be self-reliant. She wishes each home to be a center for strength in the family ties, not only when all goes well but also in times of trouble. When she is facing a problem with a patient, it is her purpose to help the patient to help himself, to help the family to meet the problem. Her experience with many similar problems, her knowledge of resources for help when the difficulties cannot be met by the patient and the family alone may be needed. Did you ever notice that when people are not well and things look black, they are inclined to think in circles? They come back to the same place again; it is not real thinking. Worry is a more suitable word for it. Such people need help in straight thinking. They need to have a plan for meeting their problems, whatever they are. It is in this planning how to meet the difficulties that arise with sickness that medical social service may be useful.

Let us take for example the child who is found to have rheumatic heart disease. There are many hundreds of such patients in New England. When the disease is active, the doctor usually tells the patient and his mother that he must stay quietly in bed for weeks, sometimes for months. There may be little or no physical pain for the patient to bear, but he must accept restriction of his activities and loss of school and play that may be more difficult to bear. Medical social service is called on by the doctor to help the mother and patient not only in carrying out the medical orders but also in making a plan with them for a way of life that may have special compensations. To meet the many needs of this family, several services are available. A visiting nurse can teach the mother how to give the child in bed the necessary care, how to keep track of his temperature, how to prepare his food. Massachusetts provides for visiting home teachers to continue education of children who are not able to go to school yet are able to do some homework. If the teacher is not available, there are often people who are willing to act as volunteer tutors for such children. But there is also the question of recreation. Children must be taught to play quiet games, to make things with their hands. Often, the child discovers abilities in modeling, painting or belt weaving that he never knew before. Or in these weeks in bed, he may be led to discover the great privileges we have in our public libraries. Reading may become a new resource for him, not only for information, but for romance and adventure. Through books, he may find that he can travel to far lands and learn of the lives of great men and women of history.

To be really healthy, we must be healthy both in body and mind. We should be making full use of all the capacities God has given us. How few of us do that! Sickness may sometimes be made a real teacher. We discover, for one thing, how precious good health is. But, if we must live with physical limitations, we have freedom to develop our minds, and through use of our latent capacities, we may find compensations for misfortune. This is what many children have taught me. I am grateful to them for their teaching.

## WAR ACTIVITIES

### UNITED STATES ARMY

The following medical officers entered on active duty between November 29 and December 13, 1941:

Wiesner, Ernest E., 1st Lieut., of Brockton, Massachusetts: Camp Edwards, Massachusetts.

Raymond, William H., Jr., 1st Lieut., of Lynn, Massachusetts: Fort Williams, Portland, Maine.

### CIVILIAN DEFENSE

Dr. Augustus Thorndike, owing to the call into active service of General Hospital No. 5, has been obliged to resign from the position of deputy medical director of the Medical Division of the Massachusetts Committee on Public Safety, and Dr. A. William Reggio, of Brookline, has been appointed to the post.

## MISCELLANY

### AIMS OF COLLAPSE THERAPY

The habit of calm appraisal characteristic of English physicians seems to be ruffled neither by the pressure of war emergencies nor by howling bombs. Tuberculosis work in England, although sometimes interrupted, continues to engage the earnest attention of physicians and laymen. American readers will profit by Pearson's clear analysis of the objects of collapse therapy in the treatment of pulmonary tuberculosis (Pearson, S. V. What are we aiming at in collapse therapy? *Tubercle* 22:159-165, 1941), an abstract of which follows:

The objects of treatment in pulmonary tuberculosis are fourfold: to arrest the progress of the disease, to heal the damaged tissues, to restore the general health and working capacity of the patient, and to render his sputum negative. Often, there is likelihood of clash between these objects, and what to do is sometimes overshadowed by the question when to do it. The aims of collapse treatment for pulmonary tuberculosis may be surveyed under eight heads.

*The constitutional effects of this disease are of more importance than the local.* The constitutional symptoms, rather than damage to the lungs, endanger life and health. But the successful treatment of the local lesion is the way to allay the constitutional symptoms. The characteristic feature of the disease, a series of reactions in the connective tissues, only secondarily affects the functions of the breathing apparatus. It is the exudative lesions that produce the most dangerous symptoms, and are most amenable to collapse therapy, although it is not yet known how such therapy affects them.

*Its chief characteristic is that it produces reactions in the connective tissues.* Aside from its effect on gross lesions, including cavities, collapse therapy produces ischemia, passive hyperemia and lymphatic stasis, which encourage proliferation of connective tissues and the production of fibrosis in early lesions. It is well to emphasize this because collapse therapy is too often reserved for the patient with excavation and other gross lesions. The relaxation, the ischemia and the lymphatic stasis affect the diseased parts more than the healthy. But, if the toxemia is lessened, the work of healthy lung tissues is eased because

the function of the latter is interfered with less than it was

*The tubercle bacillus is nearly always "master of ceremonies"* It is a mistake to be apprehensive of secondary organisms within the lesions in the lung, for the tubercle bacillus is the all important etiologic agent. It is time the bogey of mixed infection was laid to rest. The tubercle bacillus is responsible not only for early infiltration of the Asman type (early round foci) or early excavation, but also for liquefaction.

*A re-expanded, healed lung should be the aim of therapy then and as far as possible.* This means that a reversible and temporary type of collapse is to be preferred whenever possible.

*The best induced collapse is always a selective one.* So-called respiratory traumatism" (abnormal stretching of diseased parts) is based on the idea that the movements of respiration do harm to a diseased lung and that collapse treatment counteracts this harm by resting the lung. But on occasion collapse treatment may increase the harm. For example, when a stretched pleural adhesion attached viscally to the region of a cavity in the lung occurs in an artificial pneumothorax. It must ever be an aim of collapse therapy to amend and convert such a condition. The mechanisms that produce harm are those which increase the stretching of diseased parts. These must be discovered with the aid of roentgenograms and even more, by careful observations, on the screen, of respiratory movements. (Slow motion cinematography is being increasingly employed in the study of respiratory movements.)

*Collapse is obtained by relaxing tension of diseased parts.* This has long been emphasized but even now, when movements during breathing and coughing are being studied, too much attention is often given to cavities rather than to the influence of such movements on the relaxation of other pulmonary tissues.

The movements of respiration affect the diseased parts of the lung either directly or indirectly—a distinction not always easy to make. The surrounding parts can be pulmonary or nonpulmonary, and their effect on the tensions within the thorax must be considered. Collapse therapy aims at relieving these and permitting relaxation. Perhaps even more important than expansion, contraction and movement of cavities is the effect of respiratory movements on the lung tissues surrounding and in proximity to a cavity.

*In dealing with cavities, one's aim is, of course, to get rid of them.* Collapse plays a part in this by closing the bronchocavernous passage, stabilizing and reducing intracavitary pressures, starving and debilitating the tubercle bacilli on the cavity walls.

"It always strikes me," says the author, "that the hole in the lung has held far too much of the attention." Efforts to classify cavities have been useful but not inconclusive. One is often in doubt how to interpret an annular shadow. Mistakes are still made between a ring of fibrosis, a zone of reaction around a central focus and one of atelectasis. Even the supposed hole may be found to be no hole on post mortem examination. There are other difficulties. Probably the best classification of cavities is that of Coryllos: open, closed and narrowed.

Early cavities disappear sometimes without any measure to relax anything. When a cavity does not close spontaneously, collapse therapy is used. Artificial pneumothorax would succeed more frequently if the suitable case were found earlier and proceeded with, especially if cauterization of adhesions were more popular. The excavated lung needs relaxation from without, that is by being de-

tached from the bony cage of the thorax, but not under too high a pressure within the cavity itself can keep the hole open, and if such air is absorbed and the compressed lung around the cavity reexpands it will fill the gap. This process is accomplished by getting the bronchial opening blocked and may occur more or less by accident. Cavity closure after an ineffectual pneumothorax occurs fairly frequently, and can be aided by a temporary phrenic operation, but the reason why the cavity closes cannot be explained. Closure may come about through a kinking of the bronchus draining the cavity although a case has been reported in which a kinking had a disastrous effect. One's aim should be to know when a kinking has occurred, when it is benefiting the patient and how it has come about.

Several lessons can be learned for collapse therapy from work with Monaldi's method, namely, the trans pleural decompression treatment of cavities. One of these has to do with the blocking of the cavity. When a cavity becomes blocked, the oxygen is absorbed, and the tubercle bacilli languish. There is good evidence to show that an aim of treatment should be to starve and debilitate the tubercle bacilli on the walls of the cavities. When that has been achieved, it remains for means to be found to allow the pericavernous tissues, either by expansion or in directly by their contractile powers, to close the cavity.

*The prevention of the discharge of the bacilli.* Cavities are the main, if not the only source of the expectorated positive sputum, which augments the danger of bronchogenic spread and spread to other persons. An essential aim of treatment, therefore, is to prevent the discharge of tubercle bacilli. But the restoration of health must come first, a well trained ex-patient who behaves sensibly is not a danger. The restoration of the patient to work must not be forgotten in the desire to eliminate cavities and positive sputum.

Finally, aims should always be based on clinical and x-ray observations, which should not be directed too exclusively to cavities or to the lung condition. Collapse therapy is not purely mechanical. The many factors of the situation must be taken into account. Knowledge of collapse treatment is advancing quickly and modifying medical practice. That is the ever fascinating interest of medicine. As it progresses, certain problems are solved and discussion about them ceases, but new ones arise.—Reprinted, with changes, from *Tuberculous Abstracts*, December, 1941.

## BOOK REVIEWS

*The Political Life of the American Medical Association* By Oliver Garceau 8", cloth, 182 pp., with 14 charts. Cambridge: Harvard University Press, 1941. \$2.50

This curious book is a good example of faulty, arm chair reasoning. Apparently, the author has read widely the official publications of the American Medical Association, including the *Proceedings*, and also many publications of the various state medical journals, to which he gives repeated reference. He has also corresponded, according to his acknowledgment in a preface, with the secretaries of state and county societies, and with Olin West, secretary of the American Medical Association. Apparently, he has never taken the trouble to attend the annual sessions, particularly those of the House of Delegates, nor has he investigated at first hand the numerous activities of the association in its Chicago headquarters. His book, therefore, is decidedly lacking in factual background, and is practically valueless as an authentic or even important contribution to the subject. It would pass unnoticed ex-

cept for the fact that it emanates from the Department of Government, Harvard University, and was published by the Harvard University Press. This, indeed, appears to give it some authority. With this setting, one is surprised to find many statements of doubtful authenticity: paragraphs in which the actual meaning of a situation is twisted to make the author's point, a journalistic style not well fitted to what purports to be a scientific, logical discussion of the subject, and such a biased point of view that it takes away any force that the author might have in argument. This jejune product cannot be recommended as a book worthy of serious study.

*Infantile Paralysis: A symposium delivered at Vanderbilt University, April, 1941. Lecture 1. Poliomyelitis.* 8°, cloth, 239 pp., with 46 illustrations and 2 charts. New York: The National Foundation for Infantile Paralysis, Incorporated, 1941. \$1.25.

In April, 1941, a series of six lectures on poliomyelitis was given at Vanderbilt University under the auspices of the National Foundation for Infantile Paralysis. These lectures have now been published, and since they were given by the leading authorities in this country on various aspects of the disease, the volume presents a report on the current opinions regarding etiology, diagnosis and treatment. The essays are remarkably uniform in both style and scholarship. Because nothing of a similar nature is available in medicine and because of the timeliness as well as the broadness of these contributions, this book is an important contribution to the subject. Great credit should be given to the National Foundation for Infantile Paralysis in arranging these lectures and seeing that they were issued in printed form. The book is excellently printed, with adequate bibliographies and an index. It sells for a fraction of its actual cost.

*Electrocardiography in Practice.* By Ashton Graybiel, M.D., and Paul D. White, M.D. 8°, cloth, 319 pp., with 272 illustrations. Philadelphia and London: W. B. Saunders Company, 1941. \$6.00.

It is becoming increasingly apparent that the electrocardiograph is one of the great achievements of the twentieth century. It makes the heart sign on the dotted line and describe some of its ailments. Yet it is not an instrument on which one may press a button and have the diagnosis appear; nor is it merely a tool of the cardiologist. Rather, like the ophthalmoscope and the microscope, the electrocardiograph is an indispensable instrument in the hands of the clinician. As a result of the research that has been done, an extensive literature has accumulated on the subject. The practicing physician whose interest in cardiology has been aroused and who wishes to make the electrocardiograph part of his armamentarium finds himself in a daze. The periodic literature on electrocardiography is vast and scattered, and it is impossible for the novice to get a clear conception of the subject. Nor does the average book on cardiology cover the subject of electrocardiography sufficiently. On the other hand, some of the best books on electrocardiography are cumbersome, because of the amount of space given to the technical principles involved.

This book seems to be an answer to many a physician's prayer. It is a practical book on electrocardiography, unfettered by needless theory. The authors have eliminated the detailed descriptions of the various types of electrocardiograms, the details of technic and the underlying physiologic principles involved. After a brief introduction, the book deals with the interpretation of

electrocardiograms, normal as well as abnormal. As the authors have rightly stated, "Errors in electrocardiographic interpretation are probably more often made by calling normal variations abnormalities, than by missing real abnormalities when they are present." The authors give records of all types of variations from the normal. Practically every heart disorder is represented, including such factors as drugs that affect the electrocardiogram, or such miscellaneous conditions as anemia and trauma. Each record is printed on the right side of the book, and a short history of the patient, with an interpretation of the picture, is given on the opposite side. This is as it should be: the electrocardiogram is part of the entire clinical picture. The second part of the book is devoted to electrocardiograms for interpretation. These are records without labels, on which the physician can test himself. It is an excellent source of self-instruction. One can check himself by reading the interpretation and the history on the opposite page. Among textbooks on electrocardiography, the book stands out as one of the most practical and comprehensive. It is a valuable addition to any clinician's library.

*The Doctor Takes a Holiday: An autobiographical fragment.* By Mary McKibben-Harper, M.D. 8°, cloth, 349 pp., with 17 illustrations. Cedar Rapids, Iowa: The Torch Press, 1941. \$2.50.

Dr. McKibbin-Harper, well known for her previous travel books and for her close association with the work of the American Medical Women's Association, describes in this book her many travels to Europe and to the Orient. Her chief interest was naturally in medical conventions in which women played a prominent part, and in visits to women physicians in various parts of the world. In this book, one finds much material of value, and it is indeed a record of extensive travels by one who had an appreciative mind and who could evaluate conditions, particularly in the Orient. The illustrations are of considerable importance, since they show pictures of medical scenes, hospitals and doctors rarely found in other medical books. The volume is rather poorly printed, and there are numerous minor errors that should have been corrected. In general, it is a fairly interesting travel book by a physician.

*Clinical Aspects of the Electrocardiogram, Including the Cardiac Arrhythmias.* By Harold E. B. Pardee, M.D. Fourth edition, revised. 8°, cloth, with 219 illustrations and 14 tables. New York: Paul B. Hoeber, Incorporated, 1941. \$5.75.

The fourth edition of this popular text maintains the high standard set by its predecessors. In the eight years that have elapsed since the previous edition, new developments in the field of electrocardiography have taken place at such a rapid pace that it has been necessary practically to rewrite the whole book. In particular during this period, various thoracic leads have established their usefulness in practice, and perhaps the most important new feature is the consideration given to the precordial leads in persons with normal and with diseased hearts. The bibliography that accompanies each chapter has been selected with discrimination, and furnishes in itself a valuable guide to anyone wishing to go deeper into the subject. The book is thoroughly practical in its orientation and is presented in such a way as to be useful even to the beginner in the field.

## MIDDLESEX SOUTH AND MASSACHUSETTS MEDICINE\*

HAROLD G GIDDINGS, MD †

NEWTON CENTRE, MASSACHUSETTS

IN the brief time allotted for the delivery of this address, it is quite impossible to do more than touch in a most general way on a few of the highlights in the ninety-one years of vigorous and progressive service of the Middlesex South District Medical Society, not only to the medical profession itself, but also to the twenty six communities that are the society's component parts. From its beginning, as a unit of the Massachusetts Medical Society, as well as from earliest Colonial days, the society has always had within its ranks a group of able, progressive, vigorous and unselfish men, and in what follows an attempt has been made to describe some of the contributions that our district has made toward the advance of medicine in Massachusetts.

Following authorization by the Council of the state society, October 2, 1850, "A meeting of the Massachusetts Medical Society, residing in some thirty towns in the south part of Middlesex County, was held at Waltham on the twentieth of February [1851] to form a district medical society. The following gentlemen were chosen officers: Dr Josiah Bartlett, of Concord, president, Dr Jonathan W Bemis of Charlestown, secretary, and, Dr Edward Warren, of Waltham, treasurer."

After printing this notice in its issue of March 5, 1851, the *Boston Medical and Surgical Journal*, possibly imploringly, remarked "For the above information we are indebted to the *Daily Times* of this city. When will our medical friends learn to send such intelligence to the medical press?"

The establishment from time to time of district societies was part of the natural growth of the state society, which had come spontaneously into being in 1781. As the population of the state increased, and as new communities sprang up or older ones expanded, it was a natural sequence

that the physicians in these communities should associate themselves together in local and in district societies, for there they could enjoy the advantages of social contact, report and discuss their interesting and problem cases, the worth or worthlessness of different modes of treatment, and bring to the attention of their fellows any new discoveries that might be of value.

One subject, however, seems to have been taboo, if one may judge from excerpts taken from an address by Dr Joseph Reynolds, of Concord, at the semiannual meeting held at Waltham, November 1, 1854. Certain portions of this address are interesting, for they convey some idea of the intense feeling that existed against the homeopaths.

One subject, we trust, will be entirely ignored, unless forced upon one's attentions by inexorable fate we mean quackery. The profession have wasted enough of their strength upon this already. It is of no use to be eternally complaining that quacks abound, that people will employ them, that homeopathy is spreading in a particular district, and that some of its professors will persist in retaining their connection with our medical societies. The only way to put quackery down is to raise the standard of medical education, and thus keep all quackery *outside* of the profession where it will do no great harm. Towards accomplishing this result the members of each district society, individually and collectively, should contribute their position.

Incidentally, at about this time, the parent society was concerning itself with a study of homeopathy and its tenets, with no less a committee than Drs George Hayward, J B S Jackson and Oliver Wendell Holmes. The following resolution was accepted and passed: "That a diploma from a homeopathic institution shall not be received as an evidence of medical education, [and that] attendance at the lectures at such institutions [shall not] be regarded as qualification to entitle candidates to an examination for license from the society."

\*The Annual Orator delivered before the Middlesex South District Medical Society Cambridge May 14 1941

†Vice president Middlesex South District Medical Society

In the act of the legislature of November 1, 1781, by which the state society received its charter, no provision was made for the forming of local or district societies that should become integral parts of the parent society. In fact, the membership was limited to not more than seventy, nor less than ten, fellows, eleven constituting a quorum. In three years, however, it became evident that there was need for subsidiary committees, and a vote was taken in Mr. Furnass's room in Court Street on Wednesday, October 26, 1785, which provided for the "appointment of corresponding committees" in the several counties of the Commonwealth. These committees were designed to encourage meetings of physicians in their respective counties and the reporting of unusual or important cases, either verbally or by correspondence. Accordingly, committees were appointed for the following counties: Suffolk, Essex, Middlesex, Worcester, Hampshire, Berkshire, Bristol and Plymouth, Barnstable, Dukes and Nantucket, and Lincoln and Cumberland—for Maine was a part of Massachusetts until 1820. The first reference in the state society records to a report from the Middlesex Committee was under date of April 8, 1789. The entry reads as follows:

The corresponding committee of Middlesex reported and laid on the table a copy of the Middlesex Medical Association.

This report, signed by Isaac Rand and Oliver Prescott, addressed to Dr. N. Appleton, recording secretary, was dated April 3, 1789, and read: The committee appointed for the County of Middlesex report the enclosed printed regulations of an association of physicians, as the best means they could devise for promoting the views of the Medical Society in the county they belong to.

The printed document, which is headed "Middlesex Medical Association," is two and a half quarto pages in length, and contains ten preambles and a set of bylaws consisting of twenty articles. Despite this excellent beginning, it is impossible to trace this Middlesex Association further.

The records of the state society contain no further reference to a Middlesex association until 1844, although the *Historical Contributions of Lowell, Massachusetts* mention the fact that the first county medical association was founded in 1829, but was disbanded in 1833. Another society, which began in 1839, was merged into the Middlesex North District Medical Society in 1844.

In 1803, the legislature removed the restriction limiting membership and provided machinery for the formation of district societies. The first application was from a group of Boston men, who requested that their society be allowed to include

the "fellows residing in the neighboring towns of Charlestown, Cambridge and Roxbury." This petition was granted by the Council on February 2, 1804, but strangely enough, no further record of this group is to be found.

To obtain a proper perspective of the development of the district societies, it may be well at this point very briefly to review, in chronological order, the admission of these various units to the state society, and to note, in passing, that Middlesex South was one of the very last to become an entity. The order of admission was as follows: Worcester, 1804; Essex South, 1804 or 1805—the exact date is not given; Berkshire, 1807—although the petition for admission was granted, this society apparently never functioned, and another petition was granted in 1818, regular meetings beginning on July 1, 1819, and the charter being accepted by the state society on May 4, 1820; Hampshire, 1831; Bristol South, 1839; Barnstable and Hampden, 1840; Essex North, 1841; Middlesex North, 1844; and Suffolk and Bristol, 1849. The group consisting of Middlesex East, Middlesex South, Norfolk and Plymouth came into existence in 1850, as Franklin did in 1851, by redistricting and by petition. Worcester North was established on petition in 1858, and Norfolk South was admitted in 1884. Except for a few boundary adjustments, there have been no changes or additions in the last fifty-six years. One sometimes wonders why Charlestown and Brighton, parts of Boston, should be included in the Middlesex South, instead of in the Suffolk, District. The explanation is that, as territory surrounding Boston merged with the city, these districts became a part of Suffolk County. Charlestown, however, remained in the Middlesex South District, as Brighton, previously set off from Cambridge, did when it became part of Boston in 1874.

Of the many physicians in the history of the Middlesex South District Medical Society, some naturally attained more prominence than the majority of their fellows. In his delightful address, entitled "The Heritage of Middlesex South," which he delivered at our annual meeting in April, 1927, Dr. Dwight O'Hara reviewed in some detail the attainments and personalities of several of the more interesting of these earlier members. Because certain of them were so outstanding and so obviously influenced the course of medical thought and progress,—although their contributions were made before Middlesex South became an entity,—it seems proper again to speak of them here. One is impressed by the frequent occurrence, even in early Colonial days, of names with which we of recent times are familiar, and

which we instinctively associate with the best in medicine.

The name "Tufts" occupies a place of high honor in the state society's records. Simon, the elder, practiced in Medford from 1725, where he served as preceptor to General John Thomas, of Dorchester Heights fame. He was the father of Simon Tufts, the younger, who succeeded to his father's practice in 1746, and of Cotton Tufts, of Weymouth, who became one of the prominent founders of the Massachusetts Medical Society. Simon, the younger, although not a founder of the state society, early became interested in its affairs. He had a hand in designing the seal (1782), was a member of the first auditing and budgeting committees (1783), and was among the first to present a paper before the Society (1784).

John Brooks, also of Medford, studied with Simon Tufts, Jr. He served at Lexington and Concord and, later, in New York, rising to the rank of adjutant-general. He was an ardent supporter of Washington. After the war, he resumed practice in Medford with his old teacher, but became interested in politics, and in 1816 was elected governor of Massachusetts. He subsequently resumed practice and was president of the Massachusetts Medical Society from 1823 to 1825.

Dr. William Kneeland, of Cambridge, served from 1784 to 1786 as second president of the newly formed Massachusetts Medical Society. He was the first of a goodly number of Middlesex South men to be thus honored. Dr. Kneeland was one of a committee from the state society to attend the induction into office on October 7, 1783, of the newly appointed professors of the "Medical Institutions of Harvard University"—a very solemn occasion in Cambridge Meeting-House. As the state society and medical school had started at about the same time, the question of which should have charge of licensing prospective practitioners soon arose. Dr. Kneeland, as one of a committee representing the Society, had an active part in negotiating the matter, which was not definitely settled until 1793. With Simon Tufts, the younger, he also helped in the first audit of the Society's finances, and in preparation of the first budget.

Another example of father and son, both beloved physicians who influenced medical thought in this district, was that of the two Josiah Bartletts—the elder of whom, born in 1759, practiced in Charlestown, and the younger in Concord. Josiah, of Charlestown, was prominent in the reorganization proceedings of the state society in 1803, helping to draft and present the petition to the General Court for these changes. He also

took part in writing the new bylaws and served on committees concerned with the formation of a district society in Boston,—“to include Roxbury, Charlestown, and Cambridge,”—both in 1804 and 1809, neither of which efforts succeeded. In 1810, he delivered the annual dissertation, entitled “On the Progress of Medical Science in Massachusetts,” which was regarded as “a noteworthy paper” and in which he pointed out the stimulus that the Revolution had given to medical investigation, the advantages of the army hospital department to students in medicine, and the fact that Washington had instituted in this state the first medical examinations for candidates for practice. Two years later, in 1812, he urged that the communications of the society be published in the *New England Journal of Medicine and Surgery*, which was just starting, as the official organ of the Massachusetts Medical College, with the professors of the school as its editors, in 1813, he suggested that a committee of the state society be appointed to confer with the professors of the Harvard Medical School on the best method of arranging a uniform plan of medical education.

Marshall Spring, of Watertown, had the doubtful distinction of being the first fellow to have been disciplined by the Massachusetts Medical Society. He had joined in 1784, and at the meeting of the Council on November 5, 1788, a letter was presented by Dr. James Lloyd, an outstanding physician in Boston, accusing Dr. Spring “for conducting in an improper manner as a fellow of this Society.” The censors, Drs. Joseph Gardner, Isaac Rand, Jr., and Lloyd had “after a fair impartial hearing adjudged a pupil of Dr. Spring’s as not qualified for present admission to practice.” According to the charge, Dr. Spring had criticized the censors and taken exceptions to their ruling, and “in a most injurious manner declared his opinion that this pupil was rejected through the influence of the subscriber [Dr. Lloyd] to gratify a personal pique and animosity.” Consideration of the charges was postponed from one meeting to another, until in the presence of both accuser and accused, on June 2, 1790, the Council “voted—that all records that have been made respecting the controversy . . . be considered as expunged and done away with.”

Early in his career,—he graduated from Harvard in 1762,—Dr. Spring built up a large practice in Watertown and the neighboring territory. Although a Tory in affiliations and convictions, he was among the first to arrive at the Battle of Lexington, where he gave freely of his skill. Iconoclastic in his outlook, he seems to have enjoyed the confidence of his community and to have had

many traits that endeared him to his followers. He died in 1818, at the age of seventy-six.

To have been chosen the first professor of theory and practice of physic in the Harvard Medical School, as Dr. Benjamin Waterhouse, of Newport, was in 1782, at the age of twenty-nine, is sufficient reason for his inclusion here; in addition, his introduction of Jennerian vaccination into this country in 1800 by courageously inoculating his six children with cowpox vaccine, and subsequently with smallpox, assures him a high place among our illustrious predecessors. The knowledge that he took but little interest in the actual practice of medicine, and that he "seemed always happiest when in opposition," cannot detract from the distinction of having been the instigator of a great forward step in American medicine. He died in Cambridge in 1846.

Among the more than two hundred delegates to attend the first meeting of the American Medical Association, which was held at Philadelphia in May, 1847, was a group of thirteen from Massachusetts. These gentlemen returned obviously much impressed by what they had seen and heard, and advised hearty co-operation in carrying out the measures proposed at the convention, which, they said, "would promote the welfare of the community and elevate the character of the medical profession." Resolutions were passed by the Council to the effect that it approved the formation of a national society, that delegates be appointed to attend its next meeting, and that a committee be named to determine the number of delegates to which the Society was entitled and to nominate a list of them. It is a matter of pleasant record that the Middlesex South District Medical Society had a part in establishing the agreeable relation between the national and the state associations. This was through the appointment of Josiah Bartlett, of Concord, on the above committee.

Dr. Bartlett was the first district president, having been elected on February 20, 1851. Like his father, Josiah, of Charlestown, he was a man of positive character, who enjoyed a very large practice. In fact, that of his father and his own, overlapping one another, covered a complete century. He was a councilor for many years. As president of the state society (1862-1864), he presided over one of the few annual meetings to be held, up to this time, outside Boston, that is, at the Berkshire Medical College in Pittsfield. His chief constructive interest, as president, was in furthering the efforts of his friend Dr. Henry I. Bowditch to establish a state board of health and vital statistics, but because the Commonwealth

was busily engaged in war activities, the effort came to naught at this time.

Very shortly after establishment of the Middlesex South District and the organization of its medical society under Dr. Bartlett, its members took an active and influential part in the proceedings of the Council. Of course, many of the gentlemen who had previously been admitted to the state society were merely reclassified, and it was natural that the names of some of them should have appeared before, as well as after, the redistricting of 1850. Prominent among these members was Dr. Morrill Wyman, one of the most revered, best loved and illustrious of all Massachusetts physicians. During his long and fruitful life, which covered ninety-five years, medicine was the one object to which he bent all his energies. "Practitioner, student, investigator, at no period of his life, even to the end, did he cease to be interested in the great discoveries which, in his generation, added so much to the science of medicine." Since his character and attributes have been so well described by others, and since so many anecdotes have been told about him, merely a brief summary of his doings as a member of the state and district societies is presented.

The first mention of his participation in these activities was in connection with a vote by the Council, on February 20, 1848, authorizing the appointment of a committee of five to make plans for the next annual meeting, because it had become evident that the details involved in this undertaking required the services of a small, compact group. Dr. Wyman, as a member of this first Committee of Arrangements thus helped to inaugurate an important custom, which has been followed for ninety-two years and has contributed much to the pleasure and efficiency of the annual meetings of the state society. In 1850, or thereabouts, he devised the cannula and trocar used by Dr. Henry I. Bowditch in performing, on April 17, 1850, the first thoracentesis done in this country. In April, 1855, Dr. Wyman attended the annual district meeting as councilor; in 1856, he was elected vice-president and gave the annual address, "On Intestinal Obstruction, with Especial Reference to the Treatment"; in 1857, he was re-elected vice-president, and in 1864, he was elected censor.

At the annual meeting of the state society, held in Pittsfield in 1863, Dr. Wyman gave the annual discourse, "The Reality and Certainty of Medicine." In 1866, he read another paper at the first two-day meeting of the Society ever held.

By 1868, physicians throughout the state had become concerned with the malodorous conditions

surrounding the office of coroner. In February of that year, the Council directed the naming of a committee to "request of the Governor and his council, the appointment, when practicable, of medical men to the office of coroner, in the different districts of this state." The conditions leading up to this request are discussed later. Dr. Wyman was put on this important committee, which, the following October, reported back to the Council that it had seen the governor, Alexander H. Bullock, and had been assured by him that the Council's resolution would be considered, whenever there was a vacancy in the office of coroner. Although no immediate change was made in the system, the matter had been brought into the open, and the way paved for the abolishment, nine years later, of an antiquated, inefficient and corrupt system.

The library of the Massachusetts Medical Society, in the course of its ninety years' existence, passed through various vicissitudes. Provisions were made for it in the first bylaws of the Society, adopted April 17, 1782, and regulations put in force that today would be regarded as Hitlerian in severity. The library, apparently, was never very flourishing, never had many volumes, and was relatively little used. When the librarian reported, in 1871, that no one had consulted the books during the previous year, it was proposed that the published volumes of the society be sold to members at twenty cents a volume, and that the remaining books be deposited in some public library. Fortunately, the Boston Public Library became the repository of most of them. After this provision had been carried out, however, there still remained in the society library several copies of *Medical Communications* and other volumes. The priceless value of these books, manuscripts and records was recognized and stressed by Dr. Henry I. Bowditch, Dr. Morrill Wyman and others, with the result that in February, 1874, the care of this material was entrusted to them and to Dr. Francis Minot, as a special committee which in turn, and as a happy sequel, stimulated Dr. James R. Chadwick to found the Boston Medical Library in 1875.

The Cambridge Hospital was incorporated in 1871, but remained open only a year because of a lack of funds and interest. In 1874, as president of the corporation, Dr. Wyman headed a committee to raise money. He had grave doubts of the success of the venture, because of the services being rendered by the Massachusetts General Hospital to Cambridge, as well as to Boston, but he accepted and, as Rev. Dr. Francis G. Peabody said at the dedication of the Morrill Wyman

House on October 29, 1929, "brought to the task all that energy and intelligence which he always so freely placed at the service of his fellow citizens."

When the hospital was dedicated, on April 29, 1886, Dr. Wyman, still president, gave the address. He continued in this office until 1892. His last official act as a councilor was at the October meeting in 1902, when at the advanced age of ninety, but still keenly aware of values, he introduced a motion that an index be made of the *Medical Communications* of the Society, which had been published since 1790. The forty-page pamphlet, issued the next year, indexed both authors and subjects and has saved much time and labor to those interested in the catalogued material. Morrill Wyman House, in its quiet setting by the Charles, is indeed a fitting memorial to the beloved physician whom it honors.

Reference has already been made to the archaic and inefficient coroner system that was in operation in the State until 1877, when it was replaced by the present, and much more satisfactory, medical examiner system. Its origin, workings and inadequacies, and the contrasting efficiency of the medical-examiner system have been described by Dr. Timothy Leary, as follows:

The coroner is of purely English derivation, and the system was inherited by us from our Anglo-Saxon forebears. "The office of Coroner is of so great antiquity that its commencement is not known."

The first formal statute after Magna Charta dealing with the Coroner is that of Edward the Confessor [sic] in the year 1276. His duties were, with others, "to take a View of the Body and the Wounds and the Cuts [and by inquiring] whether the Killing was by Felony or Misadventure of the Manner of the Killing, with what Weapon, and all of the Circumstance."

With the passage of time his duties were largely limited to determining the cause and manner of death, where death was supposed to be due to violence, and to cataloguing and evaluating property, which was dead and [gift of God], or forfeited in connection with a violent death. . . .

In the early days in England the office of coroner could be held only by 'lawful and discreet knights.' In modern times the appointees, both in England and here, have often owed their preference to office to political favor and the results have been sometimes unfortunate. In Massachusetts, coroners were appointed by the governor and council and no limitation was placed on their number. On petition to the governor and council, any citizen, if he met with their approval, could become a coroner. The result of this procedure in the county of Suffolk was a series of scandals, through the appointment of unfit men, which culminated in 1877 and led to joint action by the profession and the bar, . . . for the reform of the evil

As pointed out by Theodore H. Tyndale, a lawyer who represented the bar:

London with its enormous population, had four coroners; New York with a population three times that of Boston had four, with one medical deputy each; Brooklyn, with a population one third to one half greater, had two; Philadelphia, New Orleans, and Chicago, *two* each; San Francisco, Baltimore, Washington, and Cincinnati but *one* each—a total of twenty-four for all these large cities taken together.

Suffolk County, consisting chiefly of Boston, had forty-seven coroners, . . . almost twice as many as all the above named cities combined; of the forty-three coroners in Boston, thirty-one were regular physicians and members of the Massachusetts Medical Society, two were registered as members of the Massachusetts "Eclectic Medical Society," seven were what were known as "other physicians," while four were non-professional gentlemen. Of these last, one was an auctioneer, another an insurance agent and broker, a third vended patent medicines, while the fourth figures simply as "notary public and coroner."

Facing this situation, in October, 1876, the Council voted that the President appoint a committee of five "to take into consideration the defects of the present laws relative to the appointment and practices of coroners, so far as these defects involve the Medical Profession, and to report . . . what action, if any, is advisable." The committee named consisted of an unusually strong group—Benjamin E. Cotting, J. C. How, W. L. Richardson, J. Collins Warren and William W. Wellington, of Cambridgeport. That they gave very earnest and thoughtful consideration to their problem, working in conjunction with Mr. Tynedale, is evidenced by the searching report they submitted to the Council on February 7, 1877. This report, too lengthy to be presented in detail, was well summarized by an editorial in the *Boston Medical and Surgical Journal*, which stated that:

. . . The [coroner] system is a remnant of past and obsolete usages, and is wholly unsuited to the needs of the present times; that the powers pertaining to the office of coroner are many, unrestricted, and dangerous, and that perversion of them is already notorious, the manner in which inquests are conducted being too frequently objectionable; that the number of coroners possible under the law is unlimited, and at present the appointments are far too numerous and easily obtained, many of those now holding office being totally unfit for the place, and the deeds of some being scandalous; that no redress is practicable, except through a very tedious process, "an address of both houses of the legislature to the governor," one too complicated ever to be resorted to; that the system is a very expensive one and "even when an inquest is unexceptionably made, it is absolutely useless as an aid to justice, and what is still worse, may in fact favor the escape of the guilty."

The report itself ended with the recommendation that the president name a committee of five to cooperate with committees of other interested associations, or persons, to present the matter to the legislature, and to seek reform. The same com-

mittee was appointed as before, with the addition of Dr. William Cogswell, of Bradford, president of the Society, as chairman. So energetically did they perform their task, working in conjunction with other interested groups, that on May 9, 1877, the governor signed the present Medical Examiner Act, entitled "An act to abolish the office of coroner and to provide for medical examinations and inquests in cases of death by violence." This act has stood the test of sixty-four years, and has always operated for the interests of the public.

That the members of the Middlesex South District Medical Society had long been concerned with the inadequacies and abuses of the old system is evidenced by occasional entries in the records. In April, 1864, those attending the meeting expressed pleasure that Dr. Francis H. Brown, of Cambridge, had been appointed coroner for the county and "trusted that this was the beginning of a change which would extend throughout the whole Commonwealth, until every district should be represented by a medical officer as active and competent as this gentleman." And again, in 1869, "The subject of autopsies ordered by coroners and the collection of the established fees was introduced. After an animated discussion, a committee of three was appointed to wait upon the County Commissioners and to discuss the subject with them with a view to establishing a basis for future action in such cases." Because of this interest, it was but natural that when the matter came to a head in the state society, the president should have chosen a representative from Middlesex and one who had been active in affairs of the district, Dr. William W. Wellington, of Cambridgeport. Dr. Wellington graduated from Harvard in 1832, and practiced in Cambridgeport all his life. His father had for a long period commanded the principal practice in the whole northern district of Cambridge. Dr. Wellington is described as a scholar, as an outstanding physician, and as taking an active interest in public, as well as in professional, affairs. He was, for example, for many years secretary of the Cambridge School Committee; in fact, he was sometimes referred to as "The Committee." During the two decades 1850 to 1870, his name constantly appears in the district society's records: as one of the first secretaries, as counselor, as vice-president, and in 1862, as president. For several years after that, he served as commissioner of trials. He gave the annual address before the state society in 1870, and the next year became one of the incorporators of the Cambridge Hospital. Dr. Wellington was among those who opposed admission of women to the state or district societies. This matter first arose in June,

1867, when the trustees of the Massachusetts General Hospital requested an opinion from the Council concerning the expediency of admitting female students to visit its wards. The vote of the Council, forty nine to seven against, left no doubt where it stood; and, for good measure, it also disapproved the admission of "females" to medical schools. Dr. Burrage suggests that the use of the word "female" in this instance represents a possible belief in Kipling's dictum that "the female of the species is more deadly than the male."

In October, 1872, Miss Susan Dimock, a native of North Carolina, applied for admission to the state society. She had, in 1866-1867, studied medicine at the New England Hospital for Women and Children in Roxbury, but because no medical school here would admit her, had gone to Switzerland, where she graduated from the University of Zurich in 1871. Returning to Boston, she became head of the above mentioned hospital, and in 1872 established the first training school for nurses in the United States. Dimock Street, Roxbury, was named for her. The question of Miss Dimock's eligibility was referred to a committee, of which Dr. Wellington was a member. The majority recommended that she be allowed to take the examination, but at Dr. Wellington's suggestion the matter was referred to legal counsel for guidance. On the advice thus obtained, "the committee reported in 1873, that in their opinion the society had the power to admit, or refuse to admit, females to membership," whereupon the Council voted that the censors be instructed not to admit them.

There the matter rested until June, 1875, when another committee was appointed to report whether some plan might be devised whereby women thoroughly educated in medicine and surgery might receive the rights and privileges of fellowship. This committee's report in October still showed a division of opinion, and Dr. Wellington's motion on behalf of the minority, recommending indefinite postponement, was adopted, after rather lively discussion.

The next move came as a result of resolutions passed in October, 1877, by the Middlesex South District Medical Society and presented to the Council in June, 1878. These resolutions favored granting women the privilege of examination and admitting to fellowship those properly qualified. This vote suggests that there must have been many members in his district who disagreed with Dr. Wellington's stand. No action was taken on the recommendation of the Middlesex group, however, until June, 1879. Meanwhile, a questionnaire had been sent to all members of the state

society, to obtain a general expression of sentiment in regard to admitting women to fellowship. Of the replies received, 71 per cent favored some form of recognition, and 28 per cent were opposed to any action whatsoever. The committee appointed by the president in June, 1879, to consider the Middlesex South resolutions presented, the following October, as seemed to have become customary, both majority and minority reports. Signing the former was Dr. Alfred Hosmer, of Watertown. The minority report, however, instructing the censors to admit women for examination was the one finally adopted. But despite this vote, many objections were raised, and through a series of parliamentary maneuvers, final settlement was delayed to June, 1882. At this time, after a struggle of fifteen years, the society voted to grant to properly qualified women the same privileges as to men.

In 1869, the legislature, after many requests from the state society, created a board of health, the first to be established in the United States. So efficiently did it operate, under the chairmanship of Dr. Henry I. Bowditch, that it served as a model for the rest of the country. Because it was so influential, a brief review of the events leading up to its establishment may be of interest.

Agitation for recognition of, and action regarding, public-health problems began in 1839-1840, with the report of a committee to the Council pointing out the necessity of correctly reporting all births, deaths and marriages. An act passed by the legislature in 1842, although apparently not so far reaching as the committee wished, "at least prepared the way for a more perfect system hereafter." On May 2, 1849, the legislature, at the instance of the American Statistical Society, seconded by the Massachusetts Medical Society, authorized the appointment of a committee to make a sanitary survey of the State. The commission, made up of laymen, sought and received assistance from the Council, especially regarding nomenclature of diseases and causes of death. The report of this committee, published in 1850 and spoken of as "a remarkable document," subsequently became the basis of all future health legislation. In 1857, it was proposed that each fellow make, to the secretary of his district society, an annual return on a common form of his cases of the preceding year, this report was to be abstracted and delivered to the secretary of the parent society. Because reports were received from about only one sixth of the men in active practice, the plan was modified the next year so as to provide for the registration of only "zymotic diseases," now

known as contagious diseases. These reports, covering the years 1857 and 1858, appear in the *Annual Transactions* for 1860.

In February, 1861, the state society seconded the petition of the Boston Sanitary Association to the legislature, for the establishment of a state board of health, which should have charge of "the sanitary interests of the people," and the registration of births, marriages and deaths. Anson Hooker, of Cambridge, active for many years in Middlesex South affairs, was a member of the committee representing the Massachusetts Medical Society. The legislature disregarded this petition, as it did others submitted in each of the next two years, for the "establishment of a state sanitary commission." Despite these rebuffs, however, the Society continued its pressure year after year, until finally in 1869 the legislature succumbed, and as already pointed out, set up the first board of health to be established in the United States. This board, working in conjunction with the state society, immediately became an active influence in bettering health conditions. It continued to operate as an entity until 1879, when the legislature, against the vigorous objections of Dr. Bowditch and rather shortsightedly, merged it with the State Board of Health, Lunacy and Charity. Dr. Bowditch resigned in protest, and a year later Dr. Henry Pickering Walcott, of Cambridge, was chosen health-officer. He filled this position until 1884, when he was made chairman of the Section on Health. Apparently realizing its earlier mistake, the legislature in 1886 separated the health department from the others, making Dr. Walcott its chairman. Under his able guidance, and that of the secretary, Dr. Samuel Abbott, of Wakefield, the board made great advances and became noted throughout the country. Dr. Walcott resigned in 1914, after a distinguished service of thirty-four years, when the old board became the present Department of Public Health.

That Dr. Walcott was essentially an administrator is attested by the many public offices he held. An austere and dignified presiding officer, he served for many years as chairman of the Metropolitan Water and Sewage Board, as chairman of the trustees of the Massachusetts General Hospital, as overseer, and in 1900 and in 1905, as acting president of Harvard College. He was the state society's orator in 1889, and its president from 1896 to 1898. During his term, the censors' examination of candidates in November and May was established. He and Dr. W. W. Wellington were the only physicians among the seven incorporators of the Cambridge Hospital, and in 1892, Dr. Walcott succeeded Dr. Morrill Wyman

as president of its trustees, serving until 1917. He will long be remembered as a gentleman who brought great honor to his district and state societies and remarkable administrative ability to the many positions of trust he was called on to fill.

To have served as councilor for approximately fifty years, and never to have missed an annual meeting in a long lifetime, is a rare distinction. Such was the record of Dr. Edmund H. Stevens, of Cambridge, who was a familiar figure to most of us up to the time of his death, two years ago, in his ninety-fourth year. Graduated from Harvard Medical School in 1867, he soon became a protégé of Morrill Wyman, with whom for many years he was intimately associated, and thus quickly acquired a place of prominence in his community. His name first appears as attending Council meetings about 1880. With Dr. John T. G. Nichols, he was appointed in 1886 one of the two first visiting physicians at the newly opened Cambridge Hospital. Primarily interested in surgery, he pioneered in this branch, along with Drs. Alfred Worcester, Edward R. Cutler and Henry O. Marcy. In association with Drs. Fred C. Shattuck and Samuel B. Woodward, as nominating councilor, he had a hand over a long period in the selection of properly qualified men for presidency of the state society.

In February, 1914, it was suggested that the state society abandon the separate publication of its proceedings and communications, and that, so far as possible, it publish these and all other official matters only in the *Boston Medical and Surgical Journal*. Dr. Stevens was a member of the special committee that studied and advised acceptance of the plan. When the affiliations became effective on July 1, 1914, the Society publications, begun in 1790, ceased as independent issues.

Malpractice defense and indemnity insurance are closely allied. The basis of the former in this state is an act adopted by the Massachusetts Medical Society in 1908, which follows the practice of many other state societies. It provides, under definite rules, for the defense, by the Society, of fellows against suits for malpractice, without expense to themselves. It does not, however, provide for the payment of any judgment rendered against a fellow. Because of an almost prohibitive rise in malpractice insurance rates in 1921, a movement was started to have the society provide indemnity insurance, but since its charter contained no such provision, other plans had to be considered. In October, a committee, of which Dr. Stevens was a member, was appointed to study the whole problem. Their conclusions, submitted two months later and embracing the plan now in

operation, were adopted. The plan seems to have worked satisfactorily.

A recent description by Dorothy Thompson of Winston Churchill applies so well to Dr. Stevens that I take the liberty of quoting it here: "There was something perennially young about him, as there is always something youthful about those who have done what they wanted to do, and have been happy. He had had a good life—the best life any man can have: a life of action and a life of intellect."

It is of interest to note that, in its one hundred and fifty-eight years of existence, the Massachusetts Medical Society has chosen as president no less than nine men from the Middlesex South District, whose combined terms equal eighteen years, and that sixteen of its one hundred and thirty-one orations have been delivered by men from this district. These men are as follows:

#### PRESIDENTS FROM MIDDLESEX SOUTH

William Kneeland	Cambridge	1784-1786
John Brooks	Medford	1823-1825
Josiah Bartlett	Concord	1862-1864
Alfred Hosmer	Watertown	1882-1884
Henry P. Walcott	Cambridge	1896-1898
George W. Gay	Chestnut Hill	1906-1908
Alfred Worcester	Waltham	1919-1921
Enos H. Bigelow	Frammingham	1923-1925
Charles E. Mongan	Somerville	1935-1937

#### ORATORS FROM MIDDLESEX SOUTH

John Brooks	Medford	1808
Josiah Bartlett	Charlestown	1810
Rufus Wyman	Charlestown	1830
William J. Walker	Charlestown	1845
Luther V. Bell	Somerville	1848
Horatio Adams	Waltham	1858
Morrill Wyman	Cambridge	1863
William W. Wellington	Cambridgeport	1870
Henry P. Walcott	Cambridge	1889
John T. G. Nichols	Cambridge	1893
Alfred Worcester	Waltham	1895
Zabdiel B. Adams	Frammingham	1897
John L. Hildreth	Cambridge	1906
Walter E. Fernald	Waverley	1912
Charles F. Painter	Newton	1925
Walter B. Cannon	Cambridge	1927

A detailed description of many of the other contributions made by members of Middlesex South District Medical Society to the progress of medicine in Massachusetts is impossible. Among them, to mention only a few, were the activities of G. J. Townsend, of Natick, in promoting the public-health and medical-practice acts; those of S. W. Abbott, of Newton, known for his contributions to the study of smallpox; those of George Curtis, whose administration as health officer in Newton for many years served, and will continue to serve, as a model for other cities; those of Godfrey Ryder, of Malden, chairman of a committee that in 1913 revised the Malpractice Act; those of Edward Cowles, of Waverley, under whose guidance McLean Hospital became the foremost semi-private institution of its kind in the country; and, finally, the long and efficient service rendered by Thomas M. Durrell, of Somerville, and George L. West, of Newton, as medical examiners, each of whom gave twenty eight years to this work.

Thus, the Middlesex South District Medical Society, starting out on its ninety-second year, may look back on its accomplishments with a certain amount of satisfaction and with the realization that as one of the units of the state society it has contributed its share toward the betterment of medicine in Massachusetts. And the future is bright with the assurance that the present members, inspired by the deeds of their predecessors, will meet the challenge and strive for still greater service.

270 Commonwealth Avenue

## THE HYPERACTIVE CARDIOINHIBITORY CAROTID-SINUS REFLEX AS AN AID IN THE DIAGNOSIS OF CORONARY DISEASE

### Its Value Compared With That of the Electrocardiogram

LOUIS H. SIGLER, M.D.\*

BROOKLYN, NEW YORK

**I**N a recent communication, I<sup>1</sup> pointed out that slowing or stoppage of the heart induced by pressure on the carotid-sinus region may be used as an aid in the diagnosis of coronary disease. This assumption was based on a study of 1886 patients on whom the test was performed. The findings in this series corroborated my previous observations<sup>2-4</sup> that the cardioinhibitory reflex occurs much more frequently and in higher degrees of response in males than in females and in advancing age, conditions in which coronary disease is most prevalent. In the presence of demonstrable coronary disease, the reflex occurred oftenest and in the highest degrees.

The practical value of the test in the diagnosis of coronary disease was demonstrated in a number of cases. In many, a positive test was the only evidence of the presence of such disease at the time the test was performed. The following case is an example.

**CASE 1.** A 35-year-old man began to experience recurring left precordial pain, mainly after exertion. Physical examination 4 weeks after its onset showed nothing abnormal. The size and shape of the heart were normal, the rate was about 80 per minute, and the rhythm was regular. The sounds were of good quality, and no murmurs were heard. An electrocardiogram (Fig. 1A) likewise showed nothing abnormal. Pressure on the right carotid-sinus region, however, resulted in stoppage of the heart for several seconds. Pressure on the left yielded considerable slowing. This, together with the subjective symptoms, suggested the presence of coronary disease, even though no other evidence was present. Six weeks later, the patient developed a sudden spontaneous attack of retrosternal pain radiating to the left arm, which lasted all night. The pain was not relieved by nitroglycerin but required morphine for its relief. An electrocardiogram obtained 2 weeks after the attack (Fig. 1B) showed definite changes in the 4th precordial lead characteristic of infarction. The sedimentation rate of the blood cells was 18 mm. at 30 minutes and 24 mm. at 1 hour, which corroborated the diagnosis.

In occasional cases, a markedly hyperactive cardioinhibitory carotid-sinus reflex was present during an acute stage of myocardial infarction, and on recovery, cardioinhibition was greatly diminished. The following case is illustrative.

**CASE 2.** A 63-year-old woman, who had always been well, except for a low-grade hypertension, developed

shortness of breath and precordial oppression on exertion. This became much more marked after an episode of severe spontaneous precordial oppression lasting about 30 minutes. It was accompanied by a drop in systolic blood pressure from 190 to 115. Examination 1 week later showed slight left ventricular enlargement and moderate dilatation of the aorta. The heart rate was 90, and the rhythm was regular. The first and second heart sounds were greatly diminished in intensity, and there was a rough, short systolic murmur between the 3rd left costo-

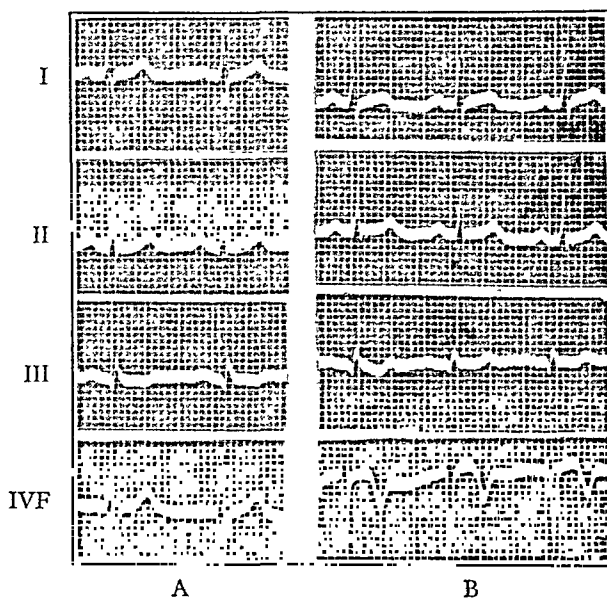

FIGURE 1.

A—normal electrocardiogram. B—electrocardiogram from the same patient eight weeks later and two weeks after an attack of coronary occlusion. The T waves in Lead 1 and the QRS complexes in Lead 3 are of lower voltage. The R waves in Lead 4 are small, and the T waves are markedly negative, whereas previously they were positive.

sternal junction and the apex. The lungs showed slight congestion at both bases. The electrocardiogram (Fig. 2A) showed low-voltage T waves in Lead 1, some depression of the RT segments and diphasic T waves in Leads 2 and 3 and abrupt QRST take-offs above the isoelectric line, with diphasic T waves, in Lead 4. The blood-cell sedimentation rate was 15 mm. at 30 minutes and 24 mm. at 1 hour. The blood pressure was 144/96. The findings definitely indicated recent myocardial infarction. Pressure on the right or left carotid sinus resulted in stoppage of the heart for several seconds.

The patient was seen again 2 months later, when the heart sounds were improved and the murmur had disappeared. The blood pressure was 162/98. The electro-

\*Attending cardiologist, Coney Island and Harper hospitals, Brooklyn, New York.

cardiogram (Fig 2B) showed positive T waves in Leads 1, 2 and 3, and markedly negative T waves in Lead 4. The RT segments in Leads 2 and 3 were slightly above the isoelectric line and rounded, and there were some changes in the QRS complexes in Lead 4. Carotid-sinus pressure at this time yielded marked slowing (+++) but no stoppage of the heart.

The patient was seen again 2 months later, when her condition had further improved. There was no precordial

occurred spontaneously and was not accentuated by exertion. At times, he also experienced some dizziness, cough and slight dyspnea. He applied for insurance disability, but his claim was rejected because the company cardiologist found his heart to be "perfectly normal."

Physical examination revealed the heart to be of normal size and shape with a rate of about 84 per minute and a regular rhythm. The heart sounds were within normal limits of intensity, quality and duration. A faint systolic

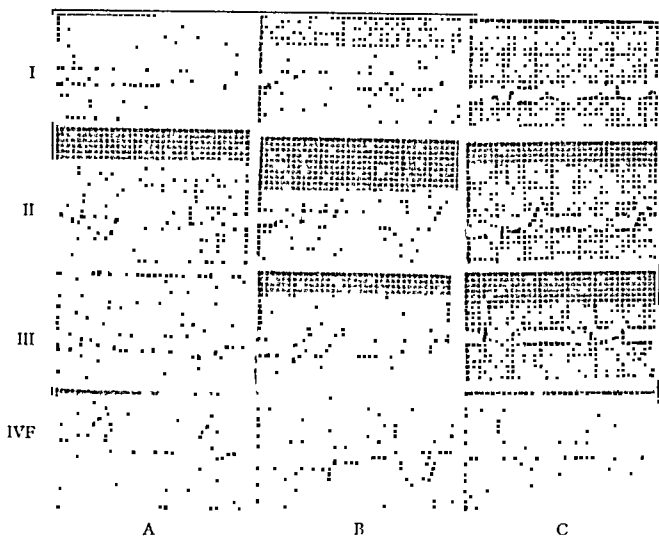

FIGURE 2

A—electrocardiogram one week after an episode of acute coronary occlusion. Biphasic T waves are noted in Leads 2, 3 and 4. B—electrocardiogram two months later. The T waves in Leads 2 and 3 are positive and in Lead 4 markedly negative. Changes are also noted in the QRS complexes in Lead 4, and in the QRS T segments in Leads 2, 3 and 4. C—electrocardiogram two months after B. Trivial T wave changes are noted in Leads 1, 3 and 4, indicating a practically static condition, with some improvement.

pain, and the heart sounds were moderately accentuated. The blood pressure was 170/94. The electrocardiogram (Fig. 2C) showed a slightly increased voltage of the T waves in Lead 1 and diminished negativity of the T waves in Lead 4. Carotid sinus pressure at this time resulted only in moderate slowing (+++).

In many cases, not only were the physical and electrocardiographic findings normal but even the subjective symptoms were not typical, and a hyperactive cardioinhibitory reflex was the only finding suggesting the diagnosis of coronary disease. The following case is an example.

CASE 3. A 60-year-old man, who was mildly diabetic, complained of occasional fleeting precordial pain, which

murmur at the apex was not transmitted. The aorta was moderately widened and tortuous, but the palpable arteries showed only a minimal amount of sclerosis. The blood pressure was 155-162/80-90. An electrocardiogram (Fig. 3) revealed nothing grossly abnormal, except for small Q waves in Lead 3, which in themselves were not significant, because the heart was transversely placed by a high diaphragm. Pressure on the right or left carotid sinus regions resulted in stoppage of the heart for several seconds. This finding, together with the presence of some aortic changes and the diabetic state, definitely suggested the presence of coronary disease.

Seven weeks after examination, the patient suddenly developed a typical attack of acute coronary occlusion and died within 1 hour.

RELATIVE FREQUENCY OF HYPERACTIVE CARDIO-INHIBITORY REFLEX AND ELECTROCARDIOGRAPHIC ABNORMALITIES IN CORONARY DISEASE

To determine the relative frequency of occurrence of the cardioinhibitory carotid-sinus reflex and of abnormalities in the electrocardiogram in coronary disease, I analyzed a series of 1073 cases showing definite evidence of such disease. Eight

FIGURE 3.

*This electrocardiogram shows normal tracings except for the presence of Q waves in Lead 3, due undoubtedly to transverse position of the heart caused by a high diaphragm, since its voltage varied with changes in respiration.*

hundred and sixty-eight of these belonged to the group previously reported,<sup>1</sup> and 205 are new cases, observed since the last series was compiled. There were 784 males and 289 females in the entire group, and all grades of the disease were represented. The criteria used in the diagnosis were the same as those described previously.<sup>1</sup>

The degrees of cardioinhibition were divided into four groups as follows: +, when the slowing was less than 10 per cent; ++, when there was 10 to 30 per cent slowing; +++, when the slowing was 30 to 70 per cent; and +++, when the heart stopped for at least three seconds. The electrocardiograms were divided into five groups, as follows: normal; left-axis deviation but otherwise normal; slight changes; moderate changes; and marked changes.

In the cases showing slight electrocardiographic abnormalities were included those with slight deviations in the QRST segment and some changes in the QRS complex, with or without left-axis deviation. The changes in the QRS complex consisted of slight slurring or notching, low voltage, excessively high voltage and the presence of a Q wave in Lead 3. In the group showing moderate abnormalities were placed cases with the following changes: considerable slurring or notching of the QRS complex, with or without prolonged intraventricular conduction time up to 0.12 second; abnormally low voltage of the QRS segment; moderate changes in the QRST segment, such as elevation or depression of more than 1.5 mm. with rounding; and a negative T wave in Lead 1 alone, a negative or diphasic T wave in Leads 2 and 3, or a negative T wave in Lead 4 alone. Many cases had more than one of these abnormalities and showed, in addition, left-axis deviation.

In the group showing marked abnormalities were placed cases with the following changes: bundle-branch block; extremely low voltage of the QRS segment, with marked notching; considerable depression or elevation of the QRST segment; and a negative T wave in all leads or at least in Leads 1, 2 and 4 or Leads 1, 2 and 3. Most of these cases also showed left-axis deviation or, occasionally, right-axis deviation.

Table 1 summarizes the incidence of the cardioinhibitory response and of the abnormalities in the electrocardiograms in the entire series of 1073 cases. It will be seen that, in the male group,

TABLE 1. The Incidences of Cardioinhibitory Response and of Abnormal Electrocardiograms in 1073 Cases of Coronary Disease.

SEX	NO. OF CASES	NO. OF CASES SHOWING CARDIO-INHIBITION	NO. OF CASES WITH ABNORMAL ELECTROCARDIOGRAMS	
			INCLUDING LEFT-AXIS DEVIATION	EXCLUDING LEFT-AXIS DEVIATION
Male	784	716 (91.3%)	619 (78.9%)	494 (63.0%)
Female	289	210 (72.6%)	257 (88.9%)	208 (71.9%)

91.3 per cent showed the cardioinhibitory reflex, whereas only 63 per cent showed abnormalities in the electrocardiogram, if cases having only left-axis deviation are excluded, or 78.9 per cent if such cases are included. Among females, about the same percentage of cases showed cardioinhibition as abnormal electrocardiograms.

A comparative analysis was also made of the various degrees of cardioinhibition and of the electrocardiographic changes. This is shown in Table 2 and Figures 4 and 5. It will be seen that

only 37.4 per cent of the male group showed significant (moderate and marked) electrocardiographic changes, whereas 61.8 per cent showed marked (+++ and ++++) cardioinhibitory reactions. In the female group, 40.0 per cent showed

nomenon, unassociated with other reflexes of the carotid-sinus group, such as a marked fall in blood pressure and cerebral manifestations, including dizziness, sensory disturbances and syncope, previously described by Weiss and his co-workers<sup>6</sup> and

gross electrocardiographic abnormalities, and 42.9 per cent marked cardioinhibition.

The table and charts also show that no relation exists between the degrees of cardioinhibition and electrocardiographic changes. The group with normal electrocardiograms showed approximately the same percentage of cases with the higher degrees of cardioinhibition as the groups with marked electrocardiographic changes.

### DISCUSSION

It appears from the findings presented here that a hyperactive cardioinhibitory carotid-sinus reflex occurs more frequently than abnormalities in the electrocardiogram in cases of coronary disease. This applies also to the higher degrees of hyperactivity, which are definitely abnormal manifestations and occur very infrequently in the absence of coronary disease. The test may therefore perhaps be considered to be of more diagnostic value than the electrocardiogram in the recognition of such disease.

Like any other test or method of examination, however, the hyperactive cardioinhibitory carotid-sinus reflex has its shortcomings and pitfalls. The facts that it does occur in cases other than coronary disease and that many cases of such disease show a negative response limit its usefulness in such diagnosis. This, however, applies also to the electrocardiogram and to all other means of diagnosis.

The test may perhaps be considered to be a definite sign in coronary disease under the following conditions: if it occurs as an independent phe-

by Smith<sup>4</sup>; if it occurs as the principal manifestation of the group of reflexes, the other signs, appearing either late or early, being dependent on this reflex for their production; and if it appears after comparatively slight pressure on the carotid-sinus region and no other vagal disturbances occur. Under such circumstances, one must assume that the selective augmentation of the induced vagal impulse is in the cardiac ganglions rather than in the ganglions of vagal centers in the medulla. If such augmentation occurred in the medullary centers, it would conceivably affect the entire vagal system rather than predominantly that of the heart.

In the present state of knowledge, only a theoretical explanation may be offered for the frequent occurrence of a hyperactive cardioinhibitory carotid-sinus reflex in coronary disease. As stated in the previous communication,<sup>1</sup> it is possible that local ischemia diminishes the resistance of the ganglions and of the myoneural junctions of the vagus nerves in the heart. Another explanation may be that the ischemic condition caused by coronary disease may produce local chemical changes that sensitize the vagal system in the heart. That there is some chemical relation between coronary disease and vagal activity is shown by the work of Loewi.<sup>7</sup> He brought forward experimental evidence to show that the vagus nerves produce a substance, which he<sup>8</sup> later considered to be identical with acetylcholine, that caused the same effect on the heart as vagal stimulation itself. The effect of the substance is neutralized by atropine. Hall, Ettinger and Banting<sup>9</sup> produced experimental coronary disease and myocardial damage in

animals by repeated injections of a 1:10,000 solution of acetylcholine daily over a period of months.

Whatever the explanation may be, I believe that the reflex has great practical value in the diagnosis

cause of the more advanced damage to the heart. The incidence of the hyperactive cardioinhibitory reflex, however, is likewise greater in such cases.

SUMMARY

A comparative study is presented of the incidence of a hyperactive cardioinhibitory carotid-sinus reflex and of electrocardiographic abnormalities in a series of 1073 cases, mostly ambulatory, of coronary disease. It was found that 91.3 per cent of the males and 72.6 per cent of the females in this series showed the cardioinhibitory response, whereas only 63 per cent of the males and 71.9 per cent of the females showed abnormalities in the electrocardiogram. High degrees of cardioinhibitory response, which are definitely abnormal, occurred in 61.8 per cent of the males and 42.9 per cent of the females. Marked electrocardiographic abnor-

FIGURE 4. The Incidence of Cardioinhibitory Response and of Abnormal Electrocardiograms in a Series of 1073 Cases of Coronary Disease.

The ordinates represent the percentage of cases responding; the abscissas represent degrees of cardioinhibition and types of electrocardiographic changes.

Degrees of cardioinhibitory response are expressed in plus marks: + when the slowing was less than 10 per cent; ++ when there was 10 to 30 per cent slowing; +++ when the slowing was 30 to 70 per cent; and ++++ when the heart stopped for at least 3 seconds.

The designations for the types of electrocardiograms are described in the text.

A represents the male cardioinhibitory responses, and B the female; C represents the male electrocardiographic findings, and D the female.

of such disease among patients in the coronary age group who present suspicious subjective symptoms.

The cases covered by this investigation are predominantly ambulatory. In hospital material, the incidence and degree of electrocardiographic changes in coronary disease are much greater, be-

FIGURE 5. Degrees of Cardioinhibition, Expressed in Percentage of Cases, in Each Type of Electrocardiogram.

The descriptions of the degrees of cardioinhibition and the types of electrocardiograms are the same as those in Figure 4. M represents males; F, females.

malities occurred in only 37.4 per cent of the males and in 40 per cent of the females.

It is believed that the hyperactive cardioinhibitory carotid-sinus reflex may be used as an aid in the diagnosis of coronary disease in persons of the coronary age who present suspicious complaints. As such, it is often of greater value than the electrocardiogram, and will suggest the correctness of the diagnosis when the electrocardiogram may be entirely misleading.

The explanation for the frequency of the hyperactive reflex in coronary disease is at the present state of knowledge purely theoretical. It may be due to local ischemia in the heart, which lowers the resistance in the vagal ganglions and in the myoneural junctions, or which produces some chemical changes that sensitize the vagus nerves locally.

## THE TREATMENT OF ANGINA PECTORIS WITH TESTOSTERONE PROPIONATE\*

### Preliminary Report

MAURICE A. LESSER, M.D.†

BOSTON

DURING the last few years, a number of observations have been reported on the genital as well as the extragenital effects of testosterone propionate. There are, however, only a few papers dealing with its action on the circulatory system. Ratschow and Klostermann,<sup>1</sup> in experimental work on rats, observed that an androgenic preparation prevented the sloughing produced by the vasoconstricting effect of ergotamine. Clinically, Arndt<sup>2</sup> reported favorable results in 8 male patients treated with testosterone propionate; 5 of these had peripheral vascular disease, and 3 had angina pectoris. Edwards, Hamilton, Duntley and Hubert<sup>3</sup> have described an increase in the cutaneous vascular bed in castrate and eunuchoid patients treated with testosterone propionate.

The effect of testosterone propionate on blood pressure in patients with hypertension is debatable, the number of cases studied being too small to be conclusive. Steinach, Peczenik and Kun<sup>4</sup> observed a significant fall in systolic pressure in 31 of 49 patients with hypertension, following treatment with either androsterone benzoate or testosterone propionate. On the other hand, Greene<sup>5</sup> found no significant change in the blood pressure levels in 21 patients who had been treated with testosterone propionate for senile enlargement of the prostate; the majority of whom had hypertension.

Edwards, Hamilton and Duntley<sup>6</sup> observed beneficial effects from testosterone propionate in peripheral vascular disease. Three patients with thromboangitis obliterans (Buerger's disease) and 4 with peripheral arteriosclerosis showed early, definite skin vascularization.

In view of these observations, 24 patients with angina pectoris were given testosterone propionate in an attempt to ascertain whether this form of treatment would influence either the frequency or the severity of the attacks.

### METHODS AND RESULTS

Since June, 1939, 20 men and 4 women, varying in age from forty to seventy-seven years, have been treated with testosterone propionate for angina pectoris. In all these patients, the diagnosis of angina pectoris was clearly established, and was based on a history of typical attacks of substernal or precordial pain precipitated by exertion or emotion and quickly relieved by rest or by nitroglycerin. Each of the patients selected for this study experienced at least one anginal attack daily, and the majority had several. Most of the patients were treated during the fall and winter months, at a time when climatic conditions made them more subject to anginal attacks. These patients were given no medication except nitroglycerin to relieve an attack, were kept ambulatory and were encouraged to perform their usual duties.

Twenty five milligrams of testosterone propionate dissolved in 1 cc. of sesame oil<sup>7</sup> was given intramuscularly every second to fifth day, depending on the frequency and severity of cardiac pain and the response to treatment, for a total of between five and twenty five injections, with an average of eleven injections. No untoward reactions were noted. The dosage was chosen arbitrarily, and it is possible that smaller amounts of the drug may give equally good results.

All patients in this series improved under testosterone propionate treatment, but the improve-

ment was much greater in the men than in the women. The latter group is as yet too small to permit proper evaluation of the significance of sex on the efficacy of this therapy.

Two patients showed definite improvement after one injection, 8 after two, 8 after three, 4 after four, 1 after five, and 1 after six. Improvement was determined by the subjective report of the patient concerning a decrease in the frequency and severity of the attacks while continuing his usual routine, and by the ability of the patient to increase his physical activity without precipitating an attack. The beneficial effect of this course of treatment has been observed for as long as twelve months after the discontinuation of therapy.

Five patients were given six consecutive injections of sterile sesame oil prior to receiving testosterone propionate, and 2 were similarly controlled after a recurrence of their anginal symptoms following their first course of the drug. None of the patients who had received sterile sesame oil alone showed any appreciable change in symptoms. This was in marked contrast to the general improvement noted in the patients treated with testosterone propionate. The contrast was particularly striking in the 2 patients who were first treated with testosterone propionate with remarkable improvement (Cases 8 and 11, Table 1), and then had a recurrence of symptoms four and seven months, respectively, after the last injection. For these new attacks, they were given placebo injections of sterile sesame oil, without clinical improvement. Following a return to testosterone propionate therapy, relief of anginal attacks was again obtained.

Of interest is the fact that in the majority of the patients there was a lowering of blood pressure during the course of testosterone propionate therapy, but it is questionable whether any significance can be attached to this.

Fluoroscopic examinations, serial kymograms and electrocardiograms showed no uniform changes resulting from this therapy.

#### DISCUSSION

Angina pectoris has been shown to be the result of myocardial ischemia, developing from a greater demand for coronary blood flow than can be supplied at the given instant.<sup>7</sup> This discrepancy between supply and demand is most frequently associated with a narrowing of the coronary arterial bed. It has further been indicated that, in cases of angina pectoris unassociated with either hypertension or valvular disease, there are occlusions of the major coronary arteries.<sup>7,8</sup> Since the pathologic basis for angina pectoris is relative anoxia of the myocardium, therapy has been directed toward improving the coronary circulation. This can be accomplished either by vasodilatation of existing vessels or by promoting collateral circulation.

Vasodilating drugs, such as nitroglycerin and the xanthine derivatives, have enjoyed widespread use in the treatment of angina pectoris. These have been shown to increase coronary flow directly by vasodilatation of the coronary arteries.<sup>9</sup> This effect, however, is only transitory.

Improved myocardial blood supply is the major desideratum in the control of angina pectoris. This problem has been approached surgically with some success, but such methods have definite limitations

because of the operative risk.<sup>10-12</sup> The observations of Gross<sup>13, 14</sup> indicate that anastomotic channels between the right and left coronary arteries develop to an increasing degree with advancing age. From more recent studies on the coronary circulation, it has become apparent that the development of these anastomotic channels is dependent on partial or complete occlusion of one or more major coronary arteries.<sup>15, 16</sup> Furthermore, in post-mortem examinations, the adequacy of such collateral circulation in some cases has been proved by the lack of significant myocardial damage in the presence of obstructive arterial lesions of long duration.<sup>7</sup> Whether the improvement noted with testosterone propionate in the treatment of patients with angina pectoris, as well as the results obtained by Edwards, Hamilton and Duntley<sup>6</sup> in the peripheral circulation, can be ascribed to the development of collateral channels is a matter of speculation.

In contrast to that of nitroglycerin, the action of testosterone propionate is not instantaneous, and does not relieve an acute attack. Its action is only gradually discernible, the majority of the patients showing clinical improvement only after several injections. On the other hand, relief obtained was persistent, ranging from two to twelve months after treatment was discontinued.

Since the initiation of this investigation, Walker<sup>17</sup> has published data on patients with cardiovascular disease; 5 of these exhibited the syndrome of angina pectoris. Treatment with testosterone propionate led to definite improvement in 4 cases, whereas 1 patient was not benefited; however, the details of treatment in this latter case were not given. Increase in exercise tolerance, decrease in severity of pain and a general increase in strength were noted as manifestations of improvement. Recently, Bonnell, Pritchett and Rardin<sup>18</sup> also reported favorable results in 5 men with angina pectoris who were treated with an androgenic substance obtained from urine.

#### SUMMARY

Twenty-four patients, 20 men and 4 women, varying in age from forty to seventy-seven years, in whom the diagnosis of angina pectoris was clearly established, were treated with testosterone propionate.

Twenty-five milligrams of the drug was administered intramuscularly every second to fifth day for a total of between five and twenty-five injections, with an average of eleven injections.

Favorable results were obtained in all cases in that the frequency, severity and duration of attacks of angina pectoris were diminished, and these patients have been able to increase their physical ac-

tivities to a considerable degree without precipitating attacks. The beneficial effects of this treatment persisted between two and twelve months after treatment was discontinued.

The improvement in the men was much greater than in the women, although the latter group is too small to permit proper evaluation.

No appreciable improvement was noted following control injections of plain sesame oil, although the same patients responded when placed on testosterone propionate therapy.

No untoward effects were observed in any of the patients studied.

Fluoroscopic examinations, serial kymograms and electrocardiograms showed no uniform changes resulting from this therapy.

In view of the therapeutic response and the absence of untoward reactions, it is believed that testosterone propionate may prove to be a valuable drug in the treatment of angina pectoris and warrants further investigation.

## USE OF THE ASPIRATING NEEDLE IN THE DIAGNOSIS OF SOLITARY RENAL CYST\*

BANCROFT C. WHEELER, M.D.†

WORCESTER, MASSACHUSETTS

THE preoperative diagnosis of solitary cyst of the kidney can rarely be made with complete assurance. It is particularly difficult and very often impossible to distinguish between cyst and tumor, for the same symptoms and physical findings may be produced by each. Hematuria is commoner with tumor, although it also occurs with cyst, in some series as high as 25 per cent being reported. Roentgenography may be helpful but is rarely conclusive, since any or all of the criteria for the x-ray diagnosis of cyst are equally applicable to tumor. These are, as defined by Braasch<sup>1</sup> and by Greenberg et al.<sup>2</sup>: a rounded bulge in the renal outline; alteration of the normal position or axis of the kidney; compression deformities of the pelvis and calyces; deformity and compression of the ureter; pressure on adjacent organs; and calcification. Braasch has summarized the situation as follows: "In most cases uncomplicated renal cyst needs no treatment. However, the difficulty of clinical differentiation between simple cyst and neoplasm is the usual cause for surgical exploration, and in fact makes such exploration necessary in almost every case of renal cyst."

It is naturally of purely academic interest to attempt clinical distinction between the two conditions if one believes that all cysts should be operated on. A difference of opinion exists on this point, some urologists holding that, if a cyst produces no symptoms, there is no need for operation. Lately, the possibility of treating cysts by aspiration has once more been discussed. In 1939, Fish<sup>3</sup> presented 2 cases that, since operation was contraindicated, were successfully treated by aspiration and instillation of 50 per cent glucose as a sclerosing agent. The glucose was used when the cyst fluid reaccumulated after a single aspiration. More recently, a series of 15 cases was reported by Dean,<sup>4</sup> who used aspiration alone as the procedure of choice. There were no complications, and the fluid did not reaccumulate.

Aspiration as a routine form of treatment has been generally regarded as unsuitable because of the possible coexistence of tumor in the same kidney. The type of tumor to be chiefly feared ap-

pears to be not a separate and distinct growth, which would be no likelier to occur in conjunction with a cyst than in any kidney, but the rare form called "hypernephric cysts." These, according to Hepler,<sup>5</sup> are cysts with thick fibrous walls containing small islands of carcinoma. The cyst fluid may be clear. Hypernephric cysts are not common, but their occurrence<sup>6</sup> constitutes the strongest argument against the routine use of aspiration therapy.<sup>7</sup> It may be noted in passing that one common form of surgical treatment—namely, excision of the extrarenal portion of the cyst and carbolicization of the remainder—may well be ineffective in this type if unrecognized. Aspiration may be employed to advantage, however, in the treatment of cases in which symptoms are distressing but operation is contraindicated.

It is in the field of differential diagnosis, I believe, that aspiration can be most valuable. The procedure is simple and, if carefully done, carries practically no risk. In fact, Dean<sup>4</sup> has performed aspiration biopsies on 150 solid renal tumors, without mishap. Since nothing is injected, the chief hazards of perirenal air insufflation are avoided. Even if operation is contemplated, the definite establishment of the diagnosis of cyst in a case in which a large mass is present may permit the operator to select the lumbar approach rather than the abdominal. Again, if one is dealing with an asymptomatic mass connected with the kidney, the finding of clear fluid on aspiration raises a distinct question of the need of operation, especially when any deterring factors exist. Before aspiration, it is, of course, essential to have satisfactory x-ray studies, including at times a barium enema, to determine definitely the anatomic relation of the colon to the cyst.

In the following cases of solitary cyst, in which the suspected diagnosis was confirmed by aspiration, neither patient was operated on. One, having been observed for sixteen months, affords some additional information concerning the rate of reaccumulation of fluid. Data on this point in the literature are inconclusive because so few cases have been followed. If, with the reporting of a

\*Presented at a meeting of the New England Section of the American Urological Association, Boston, April 24, 1941.

†Assistant visiting surgeon, Memorial Hospital, Worcester, Massachusetts.

Since presenting this paper, I have observed a case of hypernephric cyst. A patient with a mass attached to the kidney diagnosed solitary cyst by x-ray study and with clear fluid obtained on aspiration was subsequently explored because of persistent pain. The kidney was found to contain adenocarcinoma in the cyst wall and in the immediately adjacent renal tissue and was removed.

significant number of observations, it appears that reaccumulation may take years, urologists will be more inclined than at present to employ aspiration as a therapeutic measure in selected cases.

### CASE REPORTS

CASE 1. J. H. G., a 56-year-old man, entered the Worcester Memorial Hospital on December 30, 1939, complaining of painless hematuria occurring intermittently during the preceding 2 days. He had no other urinary symptoms and considered himself to be in good general health. The previous history was noncontributory, except that the patient had had an appendectomy in 1933 and a herniorrhaphy 4 years later. The urinary sediments reported during these hospital entries were normal.

The patient was moderately obese and of a plethoric type. Physical examination showed no costovertebral tenderness; neither kidney could be felt. The urine was grossly bloody, but other laboratory findings were within normal limits. Through the cystoscope, the blood was seen to be coming from the right ureteral orifice, and on ureteral catheterization, the urine from this side was bloody whereas that from the left was clear. Cultures from both kidneys were negative. A flat x-ray film showed the lower pole of the right kidney to be opposite the 3rd lumbar interspace. In the region of the upper pole, there was a large, rounded soft-tissue mass, with a sharp outline and of homogeneous density. Retrograde pyelograms showed the upper calyces of the right kidney to be displaced downward. The left kidney pelvis appeared normal. From these findings, the roentgenologist made a diagnosis of probable solitary cyst.

Largely to confirm this diagnosis, aspiration was carried out a few days later. The patient was prepared as if for a right nephrectomy, and all plans were made to proceed with this in the event of a dry tap. Under light general anesthesia, a lumbar-puncture needle was inserted below the 12th rib on the right, just lateral to the spinal muscles in a direction inward, upward and slightly forward. A definite sensation of entering a cavity was not made out; when the desired depth was reached, however, the obturator was removed, and clear yellowish fluid obtained—325 cc. being aspirated. On examination, the fluid showed the following characteristics: alkaline reaction, specific gravity 1.012, sugar 117 mg., total protein 2.4 gm. and chlorides 610 mg. per 100 cc. and a few red blood cells per high-power field in the sediment.

On the following day, the patient felt perfectly well and has been so ever since, except for a mild intermittent lumbar backache, starting on the right, and present chiefly when he is tired. This pain had never been present previously, its first occurrence being about 2 weeks following the aspiration. What connection, if any, there may be is not clear. It has become no worse in the past year. The patient had a single recurrent episode of hematuria 8 months later.

The size of the cyst has been followed at intervals. An intravenous pyelogram taken 2 days after aspiration showed neither downward displacement of the kidney nor pressure defect of the upper calyces. Instead of the large shadow previously noted, a small nub of tissue could be seen projecting from the upper pole. A month later, there was an appreciable increase in the size of this mass, and 8 months later it appeared to be about a quarter to a third as large as originally, slight depression of the upper calyces reappearing. In a recent flat x-ray film, however, 16 months after aspiration, the mass did not seem to have increased appreciably.

*Comment.* It is possible that operation must at some future time once more be considered in this case. However, if clearly related symptoms should recur, aspiration could again be done with hope of relief. The so-called "hypernephric cyst" cannot, of course, be entirely ruled out.

CASE 2. Z. R., a 61-year-old woman, was referred to the Worcester Memorial Hospital on June 12, 1940, because of the incidental finding of an abdominal mass by her physician. She had sought relief from transient headaches and dizzy spells. The history otherwise was irrelevant. The patient had always been in good general health.

On physical examination, the only positive finding of note was a mass the size of an orange in the left upper abdomen. It was rounded, smooth, movable and non-tender. The urinary sediment contained many white blood cells and cocci per high-power field. At cystoscopy, the bladder appeared characteristic of mild chronic cystitis. Specimens of urine were obtained from both kidneys, cultures subsequently showing *Staphylococcus aureus* from each. In retrograde pyelograms, the right kidney pelvis looked normal. The mass appeared attached to the lower pole of the left kidney and moved with it. The lower calyces were pushed upward slightly. A subsequent barium enema showed that the descending colon was displaced forward by the mass. Again, the roentgenologist was reasonably sure of the diagnosis of cyst.

Since the patient had no symptoms referable to the left kidney, it was decided to ascertain, if possible without operation, whether the mass was a cyst. She was accordingly prepared as for left nephrectomy, and under general anesthesia a lumbar-puncture needle was introduced lateral to the spinal muscles in the direction indicated by the x-ray films. The mass was steadied, and counterpressure exerted with the left hand. The motion of the needle with respiration was helpful in indicating that the kidney had been reached. Fluid was encountered, and about 150 cc. aspirated. No more could be obtained on attempted adjustment of the needle in the same plane, although it was realized that more fluid was almost undoubtedly present. There were no aftereffects, and the patient was discharged a few days later. She has been seen at intervals since then, the last time a month ago, or 9 months after aspiration. The mass has been palpable at all times, and showed only slight diminution in size after withdrawal of fluid. The patient remains entirely asymptomatic.

*Comment.* Aspiration in this case was purely a diagnostic procedure. Inability to withdraw more fluid may have been due to collapse of the cyst wall against the tip of the needle, to dislodgment of the needle from the cavity, or to the fact that the cyst was multilocular. Again, the possibility that this was a "hypernephric cyst" cannot be ruled out.

### CONCLUSION

Aspiration is a simple procedure of value in the differential diagnosis of solitary cyst and tumor of the kidney.

## DISCUSSION

PRESIDENT ROGER C. GRAVES: This is a very interesting paper on a subject concerning which there may well be some discussion. One must weigh all the evidence, as Dr. Wheeler has said, and consider the advisability of aspirating a lesion that may be malignant, one must also consider the possibility of the risk that may be involved in dissemination of tumorous cells along the path of the needle outside the cyst or tumor, and one must decide wherein lies the greater risk in assuming the presence of a cyst and not operating, or in assuming the possibility of a tumor and preferring surgical exploration.

DR. G. G. SMITH (Boston): I remember only too vividly a woman who had what I was sure was a cyst. I asked her to come back in six months, and she did not show up for three years, by which time she had a clearly developed large tumor of the lower pole of the kidney, she died following operation. This was some years ago but if I had heard about Dr. Wheeler's paper at that time, I might have succeeded in getting a good effect. I believe it is not always easy to differentiate tumor and cyst. A short while ago, I operated on a man who had what looked like a typical cyst, a very large, round tumor below the kidney. Braasch states that a cyst throws a denser shadow than a tumor, and this man had quite a

heavy shadow, I thought it was a cyst, but the radiologist pointed out that several spots on the outline of the mediastinum were very significant of tumor, at least of a metastasis. I operated on the patient, as I should have anyway, because it was a large tumor, and it did turn out to be a very malignant tumor. I think, however, that Dr. Wheeler's experiences should be borne in mind.

A PHYSICIAN: I should like to ask if Dr. Wheeler has used fluoroscopy in these cases and if that would aid in differentiation.

DR. C. L. DEMING (New Haven): I have often wondered why, instead of aspirating, one does not inject iodide or some such fluid which would produce a definite cystogram and might be of distinct advantage in making a differential diagnosis. Has Dr. Wheeler thought of that possibility?

DR. WHEELER (closing): I have not used fluoroscopy. I think it might help in differentiating tumor and cyst, but it would still leave a good deal of doubt in certain cases. The main point to be borne in mind, it seems to me, is the possibility of tumor, particularly the hypernephric cyst. I have never seen any in my limited experience. I should be interested to know how common they are. So far as the injection of cysts is concerned, that has been done, although I have never tried it. Fish injected air and watched the rate of reaccumulation of fluid in his 2 cysts.

## MEDICAL PROGRESS

## ABDOMINAL SURGERY

ARTHUR W. ALLEN, MD\*

BOSTON

## ANESTHESIA

**S**O CALLED "continuous" novocain spinal anesthesia, as advocated by Lemmon,<sup>1</sup> is gaining favor. The technical difficulties are not great when careful attention to details is observed. The advantages are the greater safety of the anesthetic drug used, and the short duration of the action of novocain, which makes it possible to carry out operations of any length of time. If this method is supplemented by splanchnic block from within the abdomen, it comes near the ideal sought for safe anesthesia in operations on the stomach and duodenum. It is my opinion that this method will become well standardized and will supplant the more toxic but longer lasting agents now in use for extensive procedures.

Bronchoscopy, adequately to remove secretions from the bronchial tubes in some patients after

operation, is so vital that all anesthetists should be trained in this technique. Routine removal of bronchial secretions as advocated by Haight and Ransom,<sup>2</sup> can be carried out to great advantage on the wards by the resident staff.

## SUTURE MATERIAL

It is asserted that cotton thread is a better material for ligatures and sutures than silk or catgut,<sup>3,4</sup> and the use of cotton in a wide variety of conditions during the last six months at the Massachusetts General Hospital has substantiated these claims. Cotton is easier to handle than silk, since it is slightly rougher and the knot is more easily set, also, the unused portions do not stick to the glove as those of silk do. It is easily sterilized by boiling or autoclaving. If cotton is wound on rubber tubing, the shrinkage that occurs when it is boiled compresses the tubing slightly and does not weaken the fibers. In corresponding sizes it is stronger than unwaxed silk. It is well tolerated in the tissues and is not extruded even in

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress Annual 1940* (Springfield, Ill.) no. 3. Charles C. Thomas Company, 1941. \$4.00.

\*Chief, East Surg. Cal. Serv. Co., Massachusetts General Hospital; lecturer in surgery, Harvard Medical School.

septic wounds. Farris's<sup>5</sup> conclusion, based on experiments at the University of Michigan, that cotton causes less reaction in the cornea of the rabbit than other suture materials seems clearly corroborated by clinical data. The sizes most useful are Nos. 30, 40 and 60. It should be used instead of silk for ligatures and interrupted sutures. So-called "quilting cotton" is superior to ordinary cotton thread.

#### WAR WOUNDS

New types of injury to the abdominal viscera have been reported.<sup>6</sup> The term "burst abdomen" is used. One gains the impression that internal injuries without penetration are commoner than in former wars; such injuries are probably caused more frequently by falling debris than by concussion. The majority of abdominal wounds, however, are from fragments of high-explosive shells and are penetrating. The same rules of treatment apply to these injuries as to those seen in civil life. Early intervention (within six hours) gives the best results. Careful débridement, suture of the ruptured hollow viscera and closure without drainage are advocated. Late wounds (over six hours) must usually be regarded as already infected. The use of the Miller-Abbott tube and of the sulfonamides has improved the results. Huge defects of the abdominal wall may be treated by vaseline-gauze packs, to be left in place until extruded by granulation tissue. Vaseline-impregnated canvas may be sutured to the healthy skin edges to cover a large opening in the abdominal wall. The intestines adjust themselves to this new covering and do not become adherent to it. Ogilvie<sup>6</sup> points out that three conditions present in war wounds are not commonly found in the planned abdominal wounds of civil surgery: the abdominal peritoneum is damaged, as well as incised; the number of adhesions is apt to be greatly increased; and the first operation will probably have been done by some other surgeon in another hospital than that in which permanent care is attempted.

In war wounds, the best time to operate is very early (within six hours) or very late (after six weeks). Foreign bodies should not be removed if they are small and not near a large vessel, or if they are not the cause of a urinary, fecal or biliary fistula. The transperitoneal approach should not be employed for the removal of foreign bodies if it can be avoided. Subdiaphragmatic and pelvic abscesses are the only ones needing surgical drainage. Other abscesses either make their way to the surface or are discharged into a hollow viscus. Drainage of abscesses should be delayed as long as possible. Fecal fistulas should be closed very

late unless high in the small intestine. Intestinal obstruction is always treated by a Miller-Abbott tube, and the surgical approaches are identical with those of civil surgery: early operation in small-bowel and late operation in large-bowel obstruction. Care must be exercised to make the anastomosis in a portion of healthy viable bowel. Proximal decompression should always be used in suture of the large bowel.

Gordon-Taylor<sup>7</sup> has described many bizarre abdominal injuries occurring during the bombings of London. The results illustrate the excellent organization and care of the wounded civilians during these raids. Eviscerations and other serious multiple intra-abdominal injuries were successfully treated.

#### APPENDICITIS

Numerous reports have appeared during the past year concerning this common but serious malady. By careful analyses of the results in any clinic, one can lower the morbidity and mortality. The insidious onset and the lack of predominant signs and symptoms account for the serious state in which many of these victims reach the hospital. Educational efforts have been helpful, but there is still much to be desired along these lines.

Faxon and Rogers<sup>8</sup> have dealt with the late cases of appendicitis at the Massachusetts General Hospital. These cases have been separated into two clinical groups: those in which the general peritonitis was unassociated with a mass, and those in which such a mass was present. The data in each group have been carefully studied and allow certain deductions and recommendations that should result in a lower mortality rate. If appendiceal peritonitis is present without a definite mass, operation appears to be most dangerous on the fourth and fifth days of the disease. The McBurney incision seems to be the most satisfactory type. If a mass is present, operation should be deferred, if possible, until after the seventh day, when incision and drainage are done as a primary procedure unless the appendix can easily be removed. If appendectomy is not performed, the patient must return within six weeks for an interval operation.

The routine use of Wangensteen suction in complicated acute appendicitis has long been in practice in the clinic at the Massachusetts General Hospital and many others. Ward,<sup>9</sup> who has recently emphasized this adjunct to successful treatment, reports a reduction in mortality from 5.8 to 3.0 per cent in the cases treated in the University of California Hospital. He points out that decompression by this simple procedure should be carried

out until normal peristalsis and voluntary passage of flatus take place.

Penberthy et al.<sup>10</sup> use the Miller-Abbott tube for this purpose and admit that in two thirds of their cases the tube remained in the stomach, whereas in the other third it was carried into the small intestine. By this method, they have greatly reduced the mortality in children.

Robertson,<sup>11</sup> of Toronto, has had an extraordinarily satisfactory experience with acute appendicitis in children. He attributes his excellent results to early operation provided that the appendix has not perforated. If perforation has occurred, however, operation is withheld until the patient is in good condition. The most important single factor in reducing the mortality in this group of cases is, he believes, the Miller-Abbott tube. He advises immediate use of the tube before obstruction develops.

Proper use of the sulfonamides in appendicitis with spreading infection is established. Without any doubt, this group of drugs is lowering the death rate from appendicitis. Sulfanilamide crystals—4 to 8 gm intra-abdominally and into the wound—give a high blood level within a short time. The less soluble and better tolerated sulfonamides, particularly sulfadiazine, can be used to maintain a satisfactory level for several days. Residual abscesses may occur, but are usually in the pelvis and can be drained at a later time. Drainage at the time of operation should be instituted only when a frank abscess cavity has been opened.

Woodruff and McDonald<sup>12</sup> found 146 cystic tumors of the appendix in 43,000 appendices removed at the Mayo Clinic between 1914 and 1938. Ten of these showed Grade I adenocarcinomas. The rare incidence of cancer in the appendix is interesting in that the ratio is 1:4300 cases.

#### GALL BLADDER AND BILE DUCTS

Early versus delayed operation in acute cholecystitis has continued to be a source of debate among surgeons. In an attempt to settle the matter in our own minds, certain of us<sup>13</sup> at the Massachusetts General Hospital analyzed the data bearing on the subject in a ten-year period. To clarify the terminology used in this argument, we accepted for study only patients with pain, fever, leukocytosis, right-upper quadrant mass or muscle spasm. The surgeon's note describing the gall bladder as acute and the pathologist's report of acute cholecystitis were not accepted without the foregoing criteria. Thus, we rejected the case records of about 100 patients who may have had acute inflammation of the gall bladder but who

were not sufficiently ill to fall into the classification of the serious entity usually suggested by the term "acute cholecystitis." Four hundred and fifteen cases were accepted as fulfilling these requirements. Since gangrene of the gall bladder is necessary to produce rupture and the serious complications increasing the morbidity and mortality, we further analyzed the case records on this basis.

Most of the reports deal with the time interval between admission to the hospital and operation. We believed, as Gage<sup>14</sup> did, that a better understanding of the situation could be determined if the interval between onset of symptoms and operation were regarded as the basis for study. Some of us believed that operation could be done more safely after the acute process had subsided, whereas others, for example, Miller,<sup>15</sup> were of the opinion that early surgery was indicated. This furnished sufficient data to make comparisons of the two schools of thought from our own records. Many interesting facts came to light in this study.

Rarely does a patient under the age of forty-five die following cholecystectomy. Only 2 deaths in 139 cases in this group occurred, and both were due to pulmonary embolism, proved at autopsy.

Only 10 patients had gangrenous gall bladders before the fourth day of the disease, and all recovered; there were only 3 deaths among 108 patients operated on before the fifth day of the disease. Patients operated on after the fifth day of the disease were likelier to have gangrene and perforation, and such cases were associated with a higher morbidity and mortality.

Eighty-five per cent of the patients had been admitted to the hospital during the early period of their illness. Thus, the patient and the physician were not at fault for the delay. Emergency operations in the night, usually carried out under an incorrect diagnosis, resulted in a higher mortality than those done the next morning after proper hydration and so forth.

Free rupture into the peritoneal cavity occurred in only 3 patients, with a fatal outcome in each case.

Cholecystectomy was a safer procedure than cholecystostomy, regardless of the duration of symptoms or the age of the patient. Careful study of the records failed to reveal that removal of the gall bladder would not have reduced the deaths in the group who had simple drainage. In spite of this, we still believe that a drainage operation may, on occasion, be justifiable.

It was not possible, by temperature elevation, degree of leukocytosis or any other evidence, to predict which cases would develop gangrene. One must assume that any acute inflammation of the

gall bladder may develop into gangrene, since 29.4 per cent of these gall bladders were gangrenous at operation.

Our final conclusions are: that the patient with acute cholecystitis should be operated on as soon as the diagnosis is established, fluid balance is restored, and proper operative facilities are at hand; that rarely, if ever, should the operation be considered an emergency; and that the gall bladder should be removed, simple drainage being done only when the circumstances permit a minimum operative procedure.

Berk<sup>16</sup> divided a group of cases into those operated on within forty-eight hours of onset of symptoms and those operated on after this period. The mortality rate in those operated on early was only one fourth that of the late group.

I<sup>17</sup> have previously emphasized the safety factors in gall-bladder surgery. Browne<sup>18</sup> gives further support to the conclusion that careful consideration of the anomalies of the extrahepatic-duct region is essential. In a study of 280 patients at autopsy, he observed that 92.8 per cent had normal common hepatic arteries, with the right hepatic artery passing posterior to the portal vein. Actually, he found a normal left hepatic artery in 66.7 per cent and a normal right hepatic artery in 79.7 per cent of the subjects. In 44 cases, the right hepatic artery closely paralleled the cystic duct. The anomalies of the cystic artery are not so critical from the standpoint of serious damage to the patient during cholecystectomy, but it is interesting to note that one out of three of Browne's subjects had multiple cystic arteries.

The seriousness of an anomalous right hepatic artery, particularly one that crosses anterior to the common hepatic duct, is borne out by a case in which the surgeon left a clamp on a large vessel that proved at autopsy to be the right hepatic artery; the patient succumbed in a manner commonly spoken of as a "liver death." Sutton<sup>19</sup> has produced this syndrome in animals by ligating the right hepatic artery.

Sandrini<sup>20</sup> calls attention to the frequency of anomalies of the cystic duct; such anomalies, in my opinion, account for many of the catastrophes and have some bearing on the mortality rate in gall-bladder surgery. I am sure that "liver death" should be extremely rare and that injuries to the common duct and hepatic arteries will not occur if sufficient care is exercised during the operation.

Pearse<sup>21</sup> has devised and used a vitallium tube for the repair of the common hepatic duct. Clute<sup>22</sup> and McKittrick and I have been able to use this method satisfactorily. Although it is adaptable in

a limited number of situations, it will prove helpful in some anastomoses.

Brackin and David<sup>23</sup> have devised an ingenious type of anastomosis between the biliary system and the gastrointestinal tract. This procedure is believed by the authors, from their experimental and clinical data, to reduce the hazard of stricture and ascending cholangitis following the usual anastomosis. Their technic depends on a necrotizing silk ligature through the undenuded common duct or gall bladder and the mucosa of the stomach or duodenum. This type of anastomosis may be safer from the standpoint of ascending infection, but has the disadvantage of a delay of three or four days in relieving any biliary obstruction that may exist.

#### DUODENAL ULCER

Peters<sup>24</sup> has given a helpful physiologic concept of the proper treatment of certain complications of duodenal and pyloric ulcer. Complete rest of the gastrointestinal tract eliminates vomiting and distention. Without intubation of the stomach and with nothing by mouth, the almost completely constricted pylorus or duodenum allows salivary and stomach secretions to pass. Fluids given under these conditions cause less stimulation and less retention in the stomach if they contain sufficient sodium chloride to make them isotonic with blood serum. This is of great practical value in the preoperative management of obstructing ulcer, and in the postoperative management of any abdominal procedure in preventing ileus and vomiting.

Bisgard and Nye<sup>25</sup> bring out some interesting physiologic data that are opposed to the generally practiced procedures. Gastrointestinal motility is stimulated by the application of ice to the abdominal wall and by the ingestion of hot drinks by mouth. Thus, the ice bag over an inflamed appendix may be harmful. Heat applied to the abdominal wall inhibits gastrointestinal motility, as iced water taken by mouth does. Ice applied externally increases free and total gastric acidity. The ingestion of iced water diminishes the secretion of acid in the stomach. It is further claimed that dipping the patient's hands in iced water produces a stimulation of gastric acidity comparable to that of histamine.

Perforated peptic ulcer has been reviewed by Griswold and Antoncic,<sup>26</sup> and 111 consecutive cases treated in Louisville, Kentucky, were studied; there were 20 deaths in the series. They stress the importance of culturing the free fluid in the abdomen. In 18 cases with positive cultures for streptococci, there were 8 fatalities from peritonitis.

The authors recommend removal of the fluid by suction, closure of the perforation, 5 to 10 gm. of sulfanilamide powder intra-abdominally and 3 to 5 gm. in the wound, silk closure of the wound without drainage and Wangensteen suction. If the culture reveals streptococcus, sulfanilamide therapy is continued.

Ulfelder<sup>27</sup> has reviewed the cases of perforated peptic ulcer for a fifteen-year period at the Massachusetts General Hospital. The results in the last five years have not been better than those in the first five-year period of the study. Most patients surviving operation more than twelve hours after the onset of symptoms were found to have already sealed their perforation. This fact favors the use of the conservative measures of Wangensteen suction and ochsnerization in late cases. The yearly mortality curve roughly parallels the pulmonary infection death rate for Massachusetts.

Williams and Hirtzell<sup>28</sup> offer a suggestion that may prove of great value in the diagnosis of acute perforated ulcer. They state that roentgenograms taken in the left lateral decubitus position show pneumoperitoneum in 88.9 per cent of cases as opposed to 77.7 per cent in the upright position.

Although surgeons have tried a wide variety of operative procedures for the cure of duodenal ulcer, all these methods have been found ultimately unsatisfactory in cases now requiring surgery except a subtotal resection, which includes the entire antrum, as well as a large segment of the fundus. It seems incredible that such an extensive operation should be necessary to relieve a patient suffering from physiologic disease of the digestive tract. This type of attack has long been routine in dealing with hyperthyroidism, yet it is still difficult to consider such radical measures when one is dealing with ulcer. Until a more simple solution is discovered, however, a small percentage of ulcer patients will be, of necessity, subjected to an elimination of the acid-hormone cells of the antrum, as well as a generous share of the acid bearing cells of the fundus. The complications of duodenal ulcer, such as perforation, massive hemorrhage, scar tissue obstruction and persistent symptoms in spite of good treatment, continue to place about 20 per cent of all patients with duodenal ulcer in the hands of the surgeon.

More evidence is being accumulated to substantiate the safety and the excellent end results when a proper partial gastrectomy has been performed on the right patient under ideal conditions. Walters, Lewis and Lemon<sup>29</sup> have reviewed the results in 212 consecutive patients and admit a careful selection for this operation. The operative mortality was 1.9 per cent, and only 2.5 per cent of

patients developed anastomotic ulcers, 83.5 per cent were well on an unrestricted regimen of activity and diet, and 14 per cent required some restriction of diet and activity. The selection of the patient, according to his ability to withstand radical operation, is a significant one in this group of cases. One may assume that the anastomotic ulcers and the small percentage of patients still under some restriction occurred in those cases in which the ideal operation could not be carried out. It is not quite clear but almost certain that the recurrent ulcers developed in patients who either had a small amount of the antrum left in situ or had insufficient fundus removed. One must be sure of a low mortality in these nonmalignant lesions, and a few uncured patients in this group are a sign of better judgment than a higher mortality rate. If one leaves the antrum in subtotal gastrectomy, as advocated by Finsterer,<sup>30</sup> the operation is safer, but one may have to pay for this immediate safety by recurrent ulcers and unrelied patients.

I am in complete accord with McKittrick<sup>31</sup> that, if the operation is technically difficult owing to the extent of the inflammatory reaction about the ulcer, or because of the type of organisms cultured from the ulcer, or if the general condition of the patient is poor, a two stage gastrectomy is justifiable. Certainly, by this method in properly selected cases, there will be a decrease in the morbidity and mortality, both almost invariably associated with difficulties arising from the duodenal stump. The first stage consists in a Finsterer exclusion procedure, and the second stage, six weeks later, in a simple removal of the antrum and pylorus. This period of rest makes the difficult part of the operation easy to do before the reactivation of remaining acid cells has produced an anastomotic ulcer. Doubtless, an occasional patient will develop this complication before the second stage is carried out, but even this is a small price to pay for the added safety of the procedure.

The complications arising from the duodenal stump are well borne out in the excellent paper by McClure and Fallis.<sup>32</sup> Three of the four deaths in their entire series were due to these difficulties. In our own clinic, we know that increased experience of the operator reduces these complications to a minimum, but it is evident that there are technical situations demanding a change of pattern at times. It seems fair to say that a careful survey of the bile ducts, in relation to the ulcer and its inflammatory extension before the decision is made regarding the type of operation planned, will safeguard the outcome more intelligently than any standardized routine procedure.

I have long been interested in denuding the remaining antral segment of its mucosa, as advocated by Bancroft,<sup>33</sup> in difficult cases of duodenal ulcer. At the Massachusetts General Hospital, this procedure has been performed in conjunction with subtotal gastrectomy for duodenal ulcer in 14 cases. Although we have had some difficulties with the thinned-out segment and a few patients have had complications arising from this source, all but one have recovered. In a recent follow-up study<sup>34</sup> of all partial gastrectomies for duodenal ulcer, we were somewhat relieved to find no recurrent or anastomotic ulcers in this small group of cases. Our evidence supports the theory that this procedure is adequate when properly done, but it is definitely a second or third choice with us at present.

The most satisfactory results in our hands have been in cases of duodenal ulcer that has nearly or completely healed by hospital treatment. This may require several weeks and should include, at the end, a week or two of ambulatory activity. Under these circumstances, resection can usually be carried to a point where sufficient normal duodenum can be obtained for an adequate closure. The convalescence is short, and the patient has the greatest chance of taking on his regular duties in life with freedom from discomfort.

#### GASTRIC ULCER AND CANCER

The difficulty in differential diagnosis between benign and malignant ulcers of the stomach has long been recognized. Sufficient emphasis has not been placed on this subject, and many gastric lesions are treated as ulcer until the opportunity for cure is lost. Eusterman<sup>35</sup> believes that the distinction between benign ulcer and carcinoma should be more carefully evaluated in each patient: the larger ulcers—over 2.5 cm. in diameter—may prove malignant, whereas the smaller ones are usually benign, particularly in the younger patient. He advises careful watching of the patient until complete healing takes place, and warns that achlorhydria means cancer. He further states that benign gastric ulcer responds well to medical treatment.

Holman and Sandusky<sup>36</sup> also call attention to the diagnostic error in gastric lesions. In their clinic, the error was 15 per cent when any one diagnostic procedure alone was used. They report a mortality rate of 6.3 per cent in partial gastrectomy for these lesions.

We<sup>37</sup> have analyzed the records of the gastric-ulcer cases at the Massachusetts General Hospital over a ten-year period. It was surprising to find

the diagnostic error as high as 35 per cent. The clinician, the roentgenologist and the gastroscopist preoperatively, as well as the surgeon at the time of operation, were all frequently incorrect in their diagnoses. We studied the acidity on this group and found that patients with "ulcer-cancer" had just as high levels as those with benign ulcer. Acidity was frequently present in typical gastric carcinoma, but achlorhydria was almost pathognomonic of cancer. The age of the patient and the duration of symptoms were important. Patients developing symptoms after forty-five were five times as likely to have cancer as ulcer. Patients of this same age group who had had symptoms over five years were likelier to have ulcer than cancer. The results of partial gastrectomy for ulcer were excellent: only 2 patients in a group of 51 had recurrence of ulcer symptoms. Although the mortality rate for the hospital for radical operation was 6 per cent, we have done forty-two consecutive partial gastrectomies in this ulcer-cancer group, with a single death.

Patients with obvious cancer of the stomach and an operable lesion have a 20 per cent chance of a five-year cure,<sup>38</sup> whereas those resected with the diagnosis of ulcer, but proving to have cancer, have a 40 per cent chance. This seems to be the best argument for early radical surgery in the borderline group.

#### COLON

Gibbon and Hodge<sup>39</sup> have presented another strong appeal for preliminary decompression by cecostomy or colostomy followed by aseptic anastomosis after resection of large-bowel tumors. In a collected group of cases reported by several clinics, the mortality rate was 14 per cent. A comparable series operated on by the exteriorization or obstructive-resection method, commonly called the Mikulicz operation, gave a mortality rate of 27 per cent. Cattell<sup>40</sup> reports from the Lahey Clinic, where the exteriorization operation is routine, a mortality rate of 13 per cent. Thus, in the hands of experts, the two methods have a comparable risk. The morbidity is less in the primary-anastomosis group, and the operability is the same in the hands of experienced surgeons in this field. Either of these satisfactory methods gives better results than open anastomosis in the average case. The latter procedure should be used only after thorough cleansing of the involved bowel by preliminary proximal drainage.

Firor and Poth<sup>41</sup> report on the results of preliminary preparation of bowel lesions with sulfanilylguanidine. Although there is some evidence that

this drug diminishes the number of colonies of pathogenic organisms in the bowel, it is not thought to be of great value by Stone,<sup>42</sup> who has discontinued its use after an experience with 25 cases. The local use of sulfanilamide following large bowel resection seems to be of value.

Toiydzé,<sup>43</sup> by animal experimentation, has shown that thrombosis of venous collaterals due to trauma, infection and postoperative hemorrhage accounts for some of the failures at the suture line in colon anastomosis. I am sure that removal of the fatty appendages preliminary to bowel suture is unwise, and that the anastomosis should be done with these intact and without disturbance of the blood supply to the segment coming through the fatty attachments. At the Massachusetts General Hospital, we have recently encountered an anomalous blood supply to the transverse colon. This has caused us to take into account such a possibility and to modify our usual procedure in midtransverse colonic lesions. If the disease requires removal of the midtransverse colon, the preliminary operation should be anastomosis between the ileum and descending colon, or a cecostomy. Exteriorization of this midsegment, with all the disadvantages of prolonged morbidity and secondary closure, would be justified. We are convinced that anastomosis between the ileum and distal transverse colon followed by extirpation of the entire right bowel at a later date should not be the operation of choice. This method is safe and preferable in all lesions up to the midtransverse colon.

Eggers<sup>44</sup> has reported a group of 82 patients with diverticulitis of the sigmoid whom he has personally observed. 44 per cent developed serious life threatening conditions; 24 per cent had acute perforation with abscess formation or peritonitis with fatal outcome in exactly half of such complications. Five of the 82 cases had associated carcinoma. There were no deaths in a group of 23 patients operated on at a time of election; of 8 who had resection, 2 had associated cancer. The total mortality in the entire group was 20 per cent. Egger's analysis of the symptoms and signs of diverticulitis is of interest, particularly since it shows that approximately 20 per cent of such patients have bleeding.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 28021

#### PRESENTATION OF CASE

A fifty-four-year-old Irish teamster was admitted to the hospital because of hoarseness and difficulty in swallowing.

He was well until about seven weeks before entry, when he became aware of hoarseness, unassociated with other symptoms. This persisted and grew progressively worse. Two weeks before entry, he first noted difficulty in swallowing solid foods: pieces that he swallowed lodged at the level of the larynx, requiring manipulation of the trachea to make them pass. This dysphagia grew worse, although the patient had no trouble in swallowing liquids. His diet was therefore limited to fluids. At about the same time, there was onset of a tickling sensation in the throat, leading to repeated dry coughing. After a while, the cough became productive of yellow-brown sputum. During the last two weeks, dyspnea appeared, at first only on exertion, but later at rest as well. In the two nights preceding entry, the patient was kept awake by dyspnea and orthopnea. He noted that the "choking" spells occurred especially when he lay on his right side. During the night before entry, he coughed up bright-red blood three times, to a total amount of about five tablespoonfuls. There was a loss of considerable weight during his illness, although the appetite remained good.

The past and family histories were irrelevant.

On admission, the patient appeared about ten years older than his actual age; he was well developed and nourished, despite recent weight loss. He was florid faced, with poor visual acuity and sclerotic fundi. The teeth were carious. The trachea was deviated markedly to the right. The chest was barrel shaped. Respirations were slightly labored, with "leopard-growl" sounds and rhonchi transmitted throughout both lungs. The heart was within normal limits of size, with somewhat distant sounds. The abdomen was soft, with the liver palpable on deep inspiration. The prostate gland felt enlarged, but smooth and of average consistence.

The temperature was 100°F., the pulse 80, and the respirations 25. The blood pressure was 170 systolic, 100 diastolic.

Examination of the blood showed a red-cell count of 3,460,000 with 8.5 gm. hemoglobin, and a white-cell count of 9000 with 72 per cent polymorphonuclears. The blood Hinton reaction was negative. The serum protein was 6.5 gm. per 100 cc., the chlorides 97.4 milliequiv. per liter, and the vitamin C level 0.1 mg. per 100 cc. The urine was normal.

Roentgenograms of the chest showed incomplete collapse of the right lower lobe, with apparently dilated bronchi included in the lobe. The middle lobe was likewise decreased in size. The mediastinum was displaced slightly to the right, and showed marked inspiratory shift toward the right. A soft-tissue mass 5 cm. in diameter occupied the left upper mediastinum and seemed to involve the wall of the esophagus. Just below the crossing of the aorta, there was another defect on the left anterior wall of the esophagus, with no definitely visible soft-tissue mass. There was slight delay in the flow of barium in the region of the upper mediastinal mass, but no delay was observed in the region of the lower esophageal defect. The patient had difficulty in emptying the barium from his pharynx, and at times a small amount of barium was seen in the trachea.

The temperature fluctuated irregularly from 100 to 103°F. The patient was given glucose clyses and various vitamins. On the seventh hospital day, a bronchoscopy was performed. The left vocal cord moved partially on phonation, but was well abducted. The right vocal cord was partially paralyzed in the midline. Airway through the larynx was satisfactory. Just below the glottis, a mass of apparent tumor tissue was found arising from the left lateral and posterior walls of the trachea and occluding about two thirds to three fourths of the lumen. The bronchoscope was then passed distal to the tracheal growth, and the right bronchial tree hastily examined. It appeared only slightly narrowed in the region of the right middle and lower lobes, and no outcropping could be seen. Since it was obvious that tracheal obstruction might occur following removal of the bronchoscope, a tracheotomy was performed with the bronchoscope in place. A tracheotomy cannula was then introduced, under novocain anesthesia, as low in the midline as possible. The patient returned to the ward in good condition.

The following morning, he was fairly comfortable; during the afternoon, however, he developed increasing respiratory distress and, in spite of frequent suction performed by a special nurse, died early that evening.

## DIFFERENTIAL DIAGNOSIS

DR. LOWREY F. DAVENPORT: May we see the x-ray films?

DR. RICHARD SCHATZKI: This triangular shadow in the right cardiophrenic angle was interpreted as a lower lobe that had markedly decreased in size or was collapsed. A film with more exposure shows what appear to be dilated bronchi in this area. The septum between the upper and middle lobe is lower than normal, and in the lateral view one sees the middle lobe also somewhat decreased in size. A lesion producing the obstruction to the bronchi of the lower and middle lobes is not visible. There is, however, this mass in the mediastinum, which displaces the trachea to the right side. During fluoroscopy, the esophageal lesions described in the record were by no means so obvious as they sound in the finished report. This patient apparently had only slight difficulty in swallowing the barium. He complained of some obstruction in the region of the upper esophageal lesion in the area of the soft-tissue mass, where the trachea was pushed over to the right side and forward. The trachea is very poorly visible in this region, a fact that is adequately explained by the bronchoscopic findings. The lower esophageal lesion just below the bifurcation was even less conspicuous. There was not the slightest impairment of the passage of barium by this lesion, which could be demonstrated only when the film was taken at the moment when the barium passed by the lesion. To sum up, there were three lesions present: two involving the esophagus, and one involving the right lower and middle lobes.

DR. DAVENPORT: We are given definite information that the man had a tumor in his trachea, and we gain the additional evidence from the x-ray films that he had a tumor in his esophageal wall, and also evidence of obstruction to the bronchus of the right lower lobe; I think the only questions that need concern us are the nature of the tumor and where it arose. On a percentage basis, both cancer of the lung and cancer of the esophagus appear much more frequently in men than in women—the ratios are put as high as 10:1. Consequently, we get no particular lead there. The onset of the inspiratory symptoms and the onset of dysphagia were almost simultaneous. It is not unusual in extensive cancer of the esophagus for dysphagia to be a late manifestation, and we have seen cases with involvement of almost the entire length of the esophagus without any complaint of difficulty in swallowing until the terminal stage. We have the report from the bronchoscopy that no tumor was visible in the lower bronchial tree.

The tumor was high in the trachea, an unusual location for a primary cancer. Both benign and malignant tumors of the trachea are very rare, and I think from the information that we are safe in assuming that the growth was primary in the esophagus and that all the respiratory difficulties were the result of secondary involvement of the trachea, which is not an uncommon complication of the late stages of cancer of the esophagus.

The symptoms of the last few days, such as the acute dyspnea on change of position, suggest that there was actually a communication—a direct fistula—between the esophagus and trachea, with intermittent leakage of material from the esophagus into the trachea at times. Paralysis of the vocal cords too, on a percentage basis, is not an uncommon late complication of esophageal cancer. The bronchial narrowing in the right lower lobe might have been due to pressure from metastases or from the lower portion of the esophageal tumor.

We certainly do not have to consider benign growths or tumor arising from any other structure in that region. I should exclude a primary growth in the thyroid gland or any other structure.

My diagnosis is primary cancer of the esophagus, with all the subsequent manifestations due to involvement by both direct extension and pressure.

DR. TRACY B. MALLORY: Do you want to give your interpretation of the x-ray examination, Dr. Schatzki?

DR. SCHATZKI: I had the same difficulty that Dr. Davenport had in explaining how to connect these three lesions. I was impressed by the fact that this patient's first symptom was not difficulty in swallowing. I think it is extremely rare for a patient with cancer of the esophagus to report to a physician with any other complaint than difficulty in swallowing. Having seen several cases of cancer of the bronchus involving the esophagus secondarily and none of cancer of the lower esophagus involving the trachea secondarily, although having seen quite a few with lesions higher up that involved the trachea, I thought it was a little more likely that the primary lesion was in the bronchus and that the masses in the mediastinum were metastases; I knew that this was not much better than a guess, but I definitely believed that I had to connect all these three lesions in some way.

DR. EDWARD F. BLAND: Does the small amount of barium in the trachea mean obstruction in the esophagus?

DR. SCHATZKI: My impression was that it spilled over into the larynx because the patient had partial paralysis of the pharynx.

DR. BLAND: You did not think it evidence of a fistula at that time?

DR. SCHATZKI: No.

DR. ALLEN G. BRAILEY: How does Dr. Davenport explain the collapsed lower lung?

DR. DAVENPORT: By pressure.

DR. BRAILEY: From where? The main mass of the tumor was higher up.

DR. DAVENPORT: The patient had extensive neoplastic disease throughout the mediastinum. The whole question was where it arose. Was it primary in the respiratory tract or in the gastrointestinal tract?

DR. MALLORY: Certainly, one of the unusual features of this case is the nearly simultaneous appearance of difficulty in swallowing and difficulty in breathing.

DR. EDWARD B. BENEDICT: I saw the patient and was more impressed with the difficulty in swallowing than with hoarseness, and I should have esophagoscoped him rather than bronchoscoped him except that I was afraid of causing complete tracheal obstruction by pressure of the esophagoscope. Accordingly, I bronchoscoped him.

#### CLINICAL DIAGNOSES

Bronchiogenic carcinoma, with metastases to trachea and esophagus.

Bronchopneumonia.

#### DR. DAVENPORT'S DIAGNOSIS

Carcinoma of the esophagus, with secondary tracheal extension.

#### ANATOMICAL DIAGNOSES

Carcinoma of the esophagus, with metastasis to a mediastinal lymph node resulting in extension into the trachea and esophagus and an esophagotracheal fistula.

Bronchiectasis, chronic: right middle and lower lobes.

Acute tracheobronchitis.

Endocarditis, chronic rheumatic: aortic and mitral valves.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: Post-mortem examination showed a tumor mass, the major part of which lay between the trachea and esophagus and had spread into each of these structures secondarily. A fistulous tract connecting the esophagus and trachea had developed through the tumor. It was quite clear, however, that the tumor was not primary in either of these tubular structures at that point, whereas the second point of obstruction lower down in the esophagus, which Dr. Schatzki demonstrated, did present the characteristic picture of

primary cancer of the esophagus. A metastasis in a lymph node high in the mediastinum had extended both anteriorly and posteriorly, producing essentially all the symptoms. I doubt if the primary tumor caused any of them. The right middle and lower lobes showed very extensive and old bronchiectasis, with fibrous pneumonitis. The bronchi showed no points of narrowing, and despite the lack of any history of bronchiectasis, the lesion obviously antedated the carcinoma by many years. It is not surprising that the coincidence misled Dr. Schatzki. There was also rheumatic heart disease.

#### CASE 28022

#### PRESENTATION OF CASE

A sixty-two-year-old housewife was admitted to the hospital because of severe dyspnea.

She was in good health for many years, except for extreme obesity. About one week before entry, she began to complain of shortness of breath accompanied by cough, but no other symptoms. Four and a half hours before entry, there was sudden appearance of substernal pain, following the emotional shock of hearing war news. This pain persisted, and was soon followed by severe, increasing dyspnea and by a cough that was productive of white sputum.

The past history was irrelevant, except for a suspicion that the patient had had "high blood pressure" for some time. The family history was noncontributory.

Physical examination showed an obese, moribund woman weighing about 350 pounds whose skin was pallid, slightly cyanotic and moist from perspiration. She was comatose, and the heart sounds could not be heard. The respirations were irregular, 8 to 10 per minute, with coarse bubbling rales. The temperature was not recorded. The pulse and blood pressure could not be obtained. There was no peripheral edema.

Oxygen was administered by a Boothby mask, tourniquets were applied, and intracardiac Coramine and adrenalin were given, without effect. Death occurred fifteen minutes after entry.

#### DIFFERENTIAL DIAGNOSIS

DR. JOHN TALBOTT: The story is brief, and the clinical picture appears to be uncomplicated. The patient had no complaints until a week before death. She was obese, and was said to have had hypertension, but neither of these suggest an impending rapid exitus. One week before death, the patient had some dyspnea and a cough productive of white sputum. Presumably these were not incapacitating, and no mention is made of her seek-

ing medical advice. Five hours before death, the patient was stricken with substernal pain and severe dyspnea. She was brought to the hospital moribund. The heart sounds were inaudible, the pulse and blood pressure could not be obtained, and the lungs contained moist rales. These were all the data available, and from them we must explain the sudden death.

Massive pulmonary infarction is a possibility. If this were the correct explanation, there should be something to suggest a focus for emboli. A deep infection of the veins of the abdomen and legs is the commonest cause of pulmonary emboli. I have excluded a phlebitis because there are no grounds for suspecting it. Furthermore, the patient did not have chronic valvular heart disease and no mention is made of auricular fibrillation. It is possible that the dyspnea present during the week preceding death might have been caused by small pulmonary emboli. I have excluded pulmonary embolism, finally, because of the statement that the cyanosis was mild. A patient dying from massive pulmonary embolism is apt to be deeply cyanotic.

A dissecting aneurysm might produce a sudden death such as this, but I am disinclined to consider it seriously. There is no history of back or leg pain—merely the hypertension and sudden death.

An acute episode of myocardial anoxia seems most probable. The absence of symptoms of angina in the past does not argue against this diagnosis. It is appreciated that the first symptom of coronary occlusion may appear only a few hours before death. It is granted that coronary occlusion is less common in women than it is in men; however, the obesity and hypertension seem to counterbalance her sex. The story of dyspnea during the week before death is consistent with coronary insufficiency. In acute insufficiency, vasomotor shock is profound. This was evident from the pallid skin, slight cyanosis, sweating and failure to detect any pulse or blood pressure. Of course, the failure to hear heart sounds might have been related to the abundance of subcutaneous fat, but it was more likely because of their weak character.

The lack of laboratory data allows us to speculate what such data might have shown. No mention is made of venous distention, so that the venous pressure was presumably not elevated, as it might have been in pulmonary embolism. An electrocardiogram would have been of interest in providing information regarding a previous coronary occlusion or in detecting a cardiac arrhythmia terminally. It would have been less informative

concerning the terminal episode. A urine sample was not obtained, but we have no evidence to suggest a vascular nephritis. An x-ray film of the chest would have helped to determine the size of the heart and the presence or absence of a primary pulmonary process.

With the meager evidence available, I shall rest my argument on the most probable diagnosis: coronary insufficiency. It is possible that anatomic changes in the myocardial muscle accounted for the dyspnea before the terminal event.

#### CLINICAL DIAGNOSES

Coronary thrombosis.

Pulmonary edema.

#### DR. TALBOTT'S DIAGNOSES

Coronary sclerosis and coronary occlusion.

Old myocardial infarction.

#### ANATOMICAL DIAGNOSES

Pulmonary embolism and thrombosis.

Obesity, extreme.

Hypertrophy of the heart.

Carcinoma of the tail of the pancreas.

Cholecystitis, chronic.

Cholelithiasis.

Cortical adenoma of the adrenal gland.

Pheochromocytoma of the adrenal gland.

Congenital anomaly: bifid ureter and double renal pelvis, left.

Adenoma of kidney.

Endometrial polyp.

Endocervical polyp.

Leiomyoma uteri.

Miliary tuberculosis, healed, of spleen and liver.

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: Dr. Talbott wisely stuck to the only point that could profitably be discussed in regard to this patient: the cause of her sudden death. He quickly narrowed the question down to two possibilities: pulmonary embolism and coronary disease. He placed his bet, as the clinicians on the wards did, on coronary thrombosis. We found, however, essentially normal coronary arteries and multiple pulmonary emboli. The main pulmonary trunk was empty as far as the point of bifurcation, but both the right and left pulmonary arteries were almost completely filled with fresh thrombi, which could be traced along all their branches down to the smallest grossly recognizable vessels of each lung. Imbedded in the matrix of these fresh thrombi were numerous darker brownish-red, twisted and coiled fragments of emboli, ranging from 3 to 6 mm. in

diameter. It seems quite clear that there had been multiple small emboli and then secondary thrombosis, which had virtually completely blocked the entire pulmonary arterial tree. We did not search for the source of the emboli, because a dissection of the vascular tree of the massive nether extremities threatened to produce insuperable difficulties for the embalmer.

The heart was large, weighing 500 gm., but there were extensive subendocardial fat deposits that must have weighed 75 gm. Discounting this, the heart was probably not greatly disproportionate to the size of the body. A few patches of atheroma were found in the coronary branches, but nowhere was there significant narrowing of the lumens.

*Entirely aside from these factors, which were responsible for her death, the patient proved to be a museum of pathological curiosities. One always suspects endocrinopathy when dealing with extreme obesity. The pituitary and thyroid glands were both normal. The parathyroid glands were unusually large, but this proved to be due merely to exceptional amounts of interstitial adipose tis-*

sue, and the actual parathyroid tissue was, if anything, atrophic. One adrenal gland showed a cortical adenoma nearly 2 cm. in diameter, and the other showed a small but distinct pheochromocytoma of the medulla. There were a cortical adenoma of the kidney, endometrial and cervical polyps and multiple fibroids. The adenoma of the adrenal gland was not large enough to suggest a Cushing's syndrome, and there was nothing else to substantiate it, such as masculinization, vascular nephritis or increase in the basophilic cells of the pituitary gland. On the law of averages, one might have guessed that a woman of her configuration would have had gallstones. We found many of them enclosed in an enlarged gall bladder with thickened walls. A final total surprise was an early carcinoma of the tail of the pancreas, about 2 cm. in diameter. This was clearly of the acinar type, and consequently cannot be considered to have been a factor in her death. Two final items for the catalogue were the presence of many inactive fibrotic, almost healed, but recognizable miliary tubercles in the liver and spleen, and a congenital anomaly of the urinary tract.

## SERVICES FOR THE CARE OF CIVILIAN CASUALTIES

MASSACHUSETTS was one of the first states to set up adequate plans for the protection and medical care of the civilian population in the event of military attack, and a handbook, *Organization Medical Division and Care of Injured Civilians*, was published by the Medical Division of the Massachusetts Committee on Public Safety in September, 1941. Since then, many changes in organization have necessitated a second and revised edition that appears, in full, in this issue of the *Journal*, under the title, "Organization of Emergency Services for the Care of Civilian Casualties." The present recommendations bear the approval, in principle, of the defense councils of the five other New England states and of the American Na-

tional Red Cross. The text will be issued as a handbook, which may be obtained by application to the Massachusetts Committee on Public Safety; furthermore, additions revised to conform with conditions in some of the other New England states will be made available by their respective defense councils.

The essential points of the plan call for a central state committee with regional medical heads, who assist in the formation of local organizations. Each community has a medical committee, comprising representatives of the professions and agencies concerned with all phases of medical care. Furthermore, each community has a chief medical officer, who is responsible for *all* aspects of emergency medical care, including the organization and equipment of first-aid parties and medical first aid posts and the establishment of ambulance services, of a medical depot or depots, of casualty stations and of hospital services. In times of emergency, the chief medical officer proceeds to the report center and orders the mobile medical units—first-aid parties, medical first aid posts and ambulances—to the medical depot, and if an incident occurs, he sends these units to the site of disaster. He is also responsible for the direction of the walking wounded to medical first-aid posts or casualty stations and for the transportation by ambulance of the more seriously wounded to the hospitals organized for emergency care. Subsequent transfer of the casualties to base hospitals is a responsibility of the regional medical head, and the evacuation of those who reside in particularly dangerous areas or who are especially vulnerable to disaster—women, children, the infirm and handicapped and the aged—is carried out under the supervision of the Evacuation Division. It is emphasized that the general scheme is not rigid and that the program suitable for a rural community is necessarily different from that in a metropolitan area.

All hospitals are organizing their staffs in such a way that twenty-four-hour emergency service can be provided. In the large urban hospitals, operating teams whose members are well trained in the care of certain types of injury—for ex-

ample, burns, fractures, shock, chest injuries, facillo-maxillary injuries and so forth — are being formed. In no instance, however, has a member of the permanent hospital staff been assigned to a medical first-aid post, for in times of emergency, all staff members will be needed at the hospital.

The many local chapters of the American Red Cross are taking an extremely active part in the program. They are supplying the surgical dressings in the first-aid kit belts of the first-aid parties; they will provide and administer mobile canteens and will furnish many of the ambulances, all of which are under the direction of the chief medical officer; and they will also arrange for the temporary housing, clothing and feeding of uninjured refugees.

All in all, Massachusetts and the other New England states should be proud of the initiative and the accomplishments of the state defense councils, of the medical, dental and nursing professions and of relief agencies in providing a comprehensive and unified scheme for the care of civilian casualties.

---

## THE HUNTINGTON HOSPITAL

THE Collis P. Huntington Memorial Hospital, founded in 1912 as the hospital of the Harvard Cancer Commission, closed December 31. Fortunately, its patients will be cared for at the new Huntington Clinic at the Massachusetts General Hospital. Furthermore, the medical research laboratories, under the direction of Dr. Joseph C. Aub, have been given a generous amount of space at the Massachusetts General Hospital, and as soon as details can be arranged, the attack on the problems of growth, normal and abnormal, will be continued. The State Tumor Diagnosis Service, long maintained at the Huntington Hospital, will continue work in its present laboratories, without interruption.

As an indication of the advance that New England has made in the fight against cancer, the closing of the Huntington Hospital will mean the loss of less than 8 per cent of the beds for cancer patients, whereas fifteen years ago it would

have meant the elimination of all such beds, other than a few for terminal care. Although the Massachusetts General Hospital will provide some additional beds for cancer cases, this does not mean that the situation can be regarded complacently and that special effort must not be made to compensate for the phases of work carried on at the Huntington Hospital that have been discontinued or will be cut down.

The Huntington Hospital was the scientific parent of the Pondville Hospital at Norfolk, the cancer unit of the Westfield State Sanatorium, the Palmer Memorial Hospital — the cancer unit of the New England Deaconess Hospital — and the state-wide tumor clinics, of which Massachusetts can justly be proud. Furthermore, many of the men specially skilled in cancer therapy received their training there. Those who served as student house officers, residents and members of the staff have made good use of the knowledge gained in the wards and clinics, returning to the community many times the value of the resources given to the hospital.

Under the leadership of the late Dr. Robert B. Greenough, the hospital reached its peak of influence. His views, largely based on experience gained there, shaped to a considerable degree the course that programs aimed at the control and treatment of cancer have since followed. But the day of the small special hospital has passed. Too costly in these times to operate for the number of patients it can serve, and its place in large part taken by special provisions in the large general hospitals, it can live only if heavily endowed.

In the management of the Huntington Hospital, another factor entered. It was operated by Harvard University, an educational institution, not a hospital corporation concerned with supporting itself by income from patients. Faced with continuing deficits at the hospital and with a problem not properly within its field, the university has wisely decided to transfer the care of patients to the Massachusetts General Hospital.

The research activities of the Harvard Cancer Commission will continue. The discoveries of the past — such as the fundamental observation by

Tyzzar of the inheritance of tumor susceptibility in animals, the development of the radium emanation plant and the use of radon by Duane, the advances in knowledge of the relations of hormones to normal and abnormal growth and the isolation of growth inhibitors by Aub and his associates and the demonstration of individual human susceptibility to cancer by Warren's studies—augur well for progress in the future.

It is heartening to know not only that the research activities under Dr. Aub will be continued but that the clinical work, done so soundly and for so many years by Dr. Channing C. Simmons and the staff, will be carried on at the Massachusetts General Hospital, even though the hospital and its clinical staff have been discontinued. Hospitals, like human beings, die, but their good is not "interred with their bones."

## MEDICAL EPONYM

### LUGOL'S SOLUTION

This was described by J. G. A. Lugol (1786-1851), physician at the Hospital Saint Louis, in "Mémoire sur l'emploi de l'iode dans les maladies scrofuleuses [A Note on the Use of Iodine in Scrofulous Diseases]," which was read before the Royal Academy of Sciences at the session of June 22, 1829, and published at Paris by J. B. Baillière in the same year. The following is a translation of sentences on pages 48 and 49:

The method of preparation that I regard as most reliable is that of complete solution in distilled water . . . the amount of which vehicle I have established as one pound I then dissolve one half a grain, two thirds of a grain or one grain of iodine, to have three concentrations of this remedy at my disposal . . . Furthermore, I have sought to make this solution digestible by adding twelve grains of sodium chloride . . . I have termed the three concentrations of this solution, *iodized mineral water* No 1, No 2 and No 3

## MASSACHUSETTS MEDICAL SOCIETY

### COMMITTEE ON MATERNAL WELFARE

#### ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1940

During 1940, in Massachusetts, 219 maternal deaths were reviewed by the Section of Obstetrics

and Gynecology. The various causes of death are shown in Table 1; 2 deaths of nonpuerperal origin are included. It is very gratifying that there was a further decrease in the maternal-mortality rate: in 1939, it was 3.4 per 1000 living births, and in 1940, it was 2.8. The most striking reduction was

TABLE 1 Causes of Maternal Death.

CAUSE	NO OF DEATHS
Sepsis including abortions	48
Medical (pneumonia cardiac disease chronic nephritis and so forth)	43
Embolism	28
Hemorrhage including separated placenta and placenta previa	27
Alluminaria and eclampsia including toxemia	25
Surgical	13
Anesthesia	7
Ectopic pregnancy	3
Transfusion	8
Shock	2
Perinicious vomiting	2
Mesenteric thrombosis	2
Rupture of uterus	9
Nonpuerperal	2
Total	219

in the deaths from sepsis. in 1939, of 253 maternal deaths investigated, 74 were due to sepsis, but in 1940, only 48 were from that cause. It is very likely that chemotherapy was responsible for this improvement.

In this and subsequent issues of the *Journal*, the various cases will be analyzed briefly under their individual classifications. It must be borne in mind that many cases may be classified under one heading as well as another. For example, in an operative case in which version had been performed and in which the uterus had been ruptured, resulting in peritonitis, the death might be classified by one person as due to sepsis and by another as caused by a ruptured uterus. But an attempt has been made to classify all these deaths under the heading that seems to have been the primary cause.

### SEPSIS

Of the total number of cases classified as due to sepsis, the astounding number of 23 were caused by criminal or self-induced abortions. The state of Massachusetts would have had a remarkable record if these were not included. Seventeen of the 23 were cases investigated by the medical examiner, but in only 5 was an autopsy performed. The large number of criminal abortions simply emphasizes the serious step that any woman takes who attempts to interfere with a pregnancy that she does not want.

The deaths from cesarean section will be discussed in Dr. DeNormandie's résumé. It is in-

teresting to note that the Waters operation does not always ensure a successful outcome, since 1 patient in whom a Waters had been performed died of general sepsis.

Only 12 cases of sepsis following pelvic delivery were reported. Some of these cases were treated with chemotherapy, which again shows that, although this method of therapy has played an important part in the lowering of maternal deaths due to sepsis, it is not 100 per cent successful.

The review of the patients dying from sepsis leaves one much encouraged, particularly because injudicious operation as a contributing cause of infection was absent. The section has tried to teach conservatism, since it is well known that the more conservative obstetrics is practiced, the less will bungling operation result, with its accompanying infection.

Sepsis as a cause of maternal mortality can be lowered only by a rigorous crusade against the criminal abortionist, by a diminution in the number of cesarean sections done when the indication is not justified, by a continued emphasis on conservatism in all obstetrics, and by earlier recognition of the specific etiology of any infected case so that proper and adequate chemotherapy may be instituted immediately.

## WAR ACTIVITIES

### CIVILIAN DEFENSE

#### Medical Handbook No. 2

#### Organization of Emergency Services for the Care of Civilian Casualties\*

PREPARED BY THE MEDICAL DIVISION OF THE MASSACHUSETTS COMMITTEE ON PUBLIC SAFETY AND APPROVED, IN PRINCIPLE, BY THE STATE DEFENSE COUNCILS OF MAINE, NEW HAMPSHIRE, VERMONT, RHODE ISLAND AND CONNECTICUT AND BY THE AMERICAN NATIONAL RED CROSS

1. AIM AND PURPOSE. This handbook outlines a plan for the organization of emergency services for the care of civilian casualties in the event of an enemy attack, which would most probably come in the form of an air raid or sabotage. It also standardizes the medical equipment and personnel necessary for the care of such casualties from the time of injury through convalescence. The plan is flexible and can be adapted to a densely populated metropolitan area or to a rural community.

2. ORGANIZATION OF THE MEDICAL DIVISION. The general organization of the Medical Division of the Massachusetts Committee on Public Safety is shown in Fig. 1.

\*This handbook is a revised edition of *Medical Handbook No. 1 Organization Medical Division and Care of Injured Civilians*, published by the Medical Division, Massachusetts Committee on Public Safety. The information concerning organization and equipment supersedes that contained in the previous edition.

It is headed by a medical director† (and deputy medical director), who is chairman of a central executive committee, which is assisted by various central subcommittees (Fig. 2). Working in conjunction with the director are the regional medical heads, corresponding in number and location to regions (so-called "districts" in publications of the Office of Civilian Defense) specified by the United States Army. They are assisted by deputy regional medical heads. In Massachusetts, there are nine regions (Fig. 3), nine regional medical heads (Fig. 2) and eighteen deputy heads (Table 1), the latter corresponding to

the district societies of the Massachusetts Medical Society.

The functions of the director and his executive group are as follows: to simplify, standardize and integrate all the activities of the Medical Division; to send information and instructions to the regional medical heads and the chief medical officers or their deputies in each community; to assist and maintain a liaison with the other divisions of the Committee on Public Safety, with the Office of Civilian Defense and with the American Red Cross.

The function of the regional medical heads and the deputy regional medical heads is to assist in every way the work of the local medical organizations. They can be of assistance both in setting up the proper type of local medical committees and in helping them establish their organization and facilities. Furthermore, they are responsible for the designation of emergency and base hospitals in all communities of their respective regions. The regional heads and their deputies should go to the local communities and, by example and public addresses, should stimulate the people to organize and equip first-aid

†The names and addresses of the medical directors for the New England states are as follows: Maine—Dr. Allan Craig, Eastern Maine General Hospital, Bangor; New Hampshire—Dr. Charles H. Parsons, 33 Pleasant Street, Concord; Vermont—Dr. Charles F. Dalton, 2 Colchester Avenue, Burlington; Massachusetts—Dr. Elliott C. Cutler, Peter Bent Brigham Hospital, Boston; Rhode Island—Dr. Joseph C. O'Connell, 215 Thayer Street, Providence; and Connecticut—Dr. George M. Smith, Yale University School of Medicine, New Haven.

parties, medical first-aid posts, ambulance services, medical depots, and emergency and base hospitals.

In each region, the regional medical head is the rank-

tals and in many other ways. Furthermore, the regional medical heads and their deputies are responsible for lateral communications; that is, the chief medical officer of

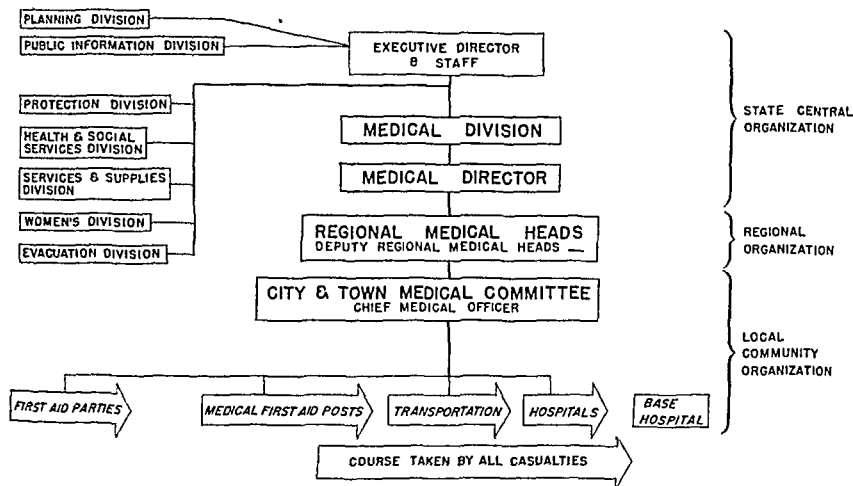

FIGURE 1. General Organization of the Medical Division

ing medical officer, and the deputy heads should assist him in every possible way. When a warning (yellow

each community suffering heavy damage should refer his request for additional personnel, supplies and equipment

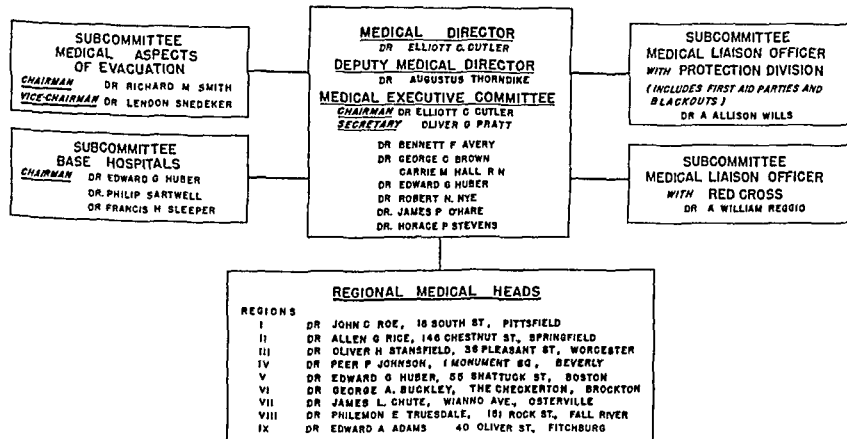

FIGURE 2. Personnel of the Central Organization of the Medical Division in Massachusetts

Since the drawing of this chart, Dr. Augustus Thorndike has resigned as deputy medical director and has been replaced by Dr. A. William Reggio, and Mr. Thomas P. Keating has been made a member of the Medical Executive Committee.

signal) comes, all should assemble at the regional headquarters; the deputy heads can be of great assistance in disseminating information to emergency and base hospi-

directly to the regional headquarters, rather than to an adjoining township. Finally, each regional head or deputy must provide an alternate to take his place, if necessary.

3. LOCAL MEDICAL ORGANIZATIONS. These vary according to the size and type of the community. There should be a medical committee in each community, with a physician as chairman, who may serve as the chief medical officer at the report center (so-called "control center" in the publications of the Office of Civilian Defense) or may appoint a deputy for this task. The chief medical officer should have complete authority over all medical services in the event of disaster and, as with every other post of the medical organization, should appoint a deputy.

On the medical committees in the large communities,

them to a *medical first-aid post* or *casualty station*. It is estimated that at least one such post is necessary for each unit of 10,000 inhabitants in any one report-center area. At the medical first-aid post will be physicians, nurses, male and female volunteers trained in first aid, and medical equipment. There, the necessary emergency medical procedures will be carried out. The patient will then be transferred, if necessary, to the designated *emergency hospital* and, later, if necessary, to a *base hospital*.

As previously mentioned, the scheme is flexible, and no set rules for organization can be established, since

FIGURE 3. Map Showing the Boundaries of the Regions and of the District Medical Societies in Massachusetts.

there should be, in addition to the chairman, one individual representing the hospitals, one representing the local board of health, one dentist and one graduate nurse, as well as other representative physicians. It is further desirable that there be a Red Cross liaison officer, a pharmacist and representatives of all agencies within the community that might render medical assistance. Each community can best judge for itself how this group should be set up.

In small communities where there are few physicians and only occasional hospitals, two, three or even four adjoining towns should unite, centering their activities on a hospital common to all and arranging for ambulance transportation of casualties to this point.

4. GENERAL OUTLINE FOR CARE OF CASUALTIES. The care of civilian casualties begins at the site of disaster. Wardens of the ARP service who have been assigned to first-aid duty will act as *first-aid parties* (so-called "stretcher teams" in the publications of the Office of Civilian Defense), rescuing the injured and directing or transporting

what should be done in a rural community is obviously different from that in a metropolitan area.

5. LOCAL ORGANIZATION FOR CARE OF CASUALTIES. Report centers have been established throughout the State, ranging in number from one in small communities to many in large cities (Fig. 4 and Appendix A). If there is more than one report center in a community, the chief medical officer must appoint a deputy chief medical officer to serve as the ranking medical officer in each report-center area.

In the event of a warning (yellow signal) at the report center, the chief medical officer, the Red Cross liaison officer (if available), the chief air-raid warden and his deputy and the heads of the other services are notified and proceed immediately thereto; the members of the mobile medical services—first-aid parties, medical first-aid posts and ambulance service—are immediately ordered by the chief medical officer to the medical depot. At the same time, members of mobile canteens and other relief services are similarly mobilized at the medical depot (relief center). When a report center is notified of an

incident by the post warden, one or more medical service units, depending on the severity of the damage, proceed immediately, on notice from the chief medical officer, to the scene of disaster. They establish a medical first aid post in a satisfactory building as near the incident as possible, preferably within 200 yards.

The necessity for the chief medical officer to organize and train the personnel of the first aid parties and medical first-aid posts to perform as co-ordinated units not only among themselves but also with the ambulance and

One of the important duties of the chief medical officer is his relation to the American Red Cross and other relief agencies. Where practicable, there should be a Red Cross representative in each report center, who will assist the chief medical officer. In many report-center areas, the Red Cross will provide, under the direction of the chief medical officer, ambulance service and mobile canteens; it will also furnish food clothes and temporary shelter to uninjured citizens rendered destitute.

**a Mobile Medical Services** A mobile medical unit consists of two first aid parties and one medical first-aid post, comprising twenty-four persons, exclusive of the ambulance drivers. Transportation of the equipment and personnel of this unit will require at least four, preferably five automobiles—one passenger car and three, preferably four, ambulances. The chief medical officer is responsible for having these vehicles in readiness. In most report-center areas, the ambulances will be provided by the local Red Cross chapters, however, many commercial ambulance companies, undertakers and others have signified their willingness to supply the necessary vehicles. Fol-

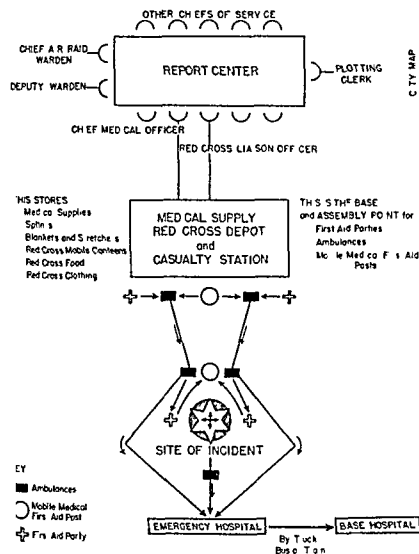

FIGURE 4 Community Organization at and from the Report Center

emergency hospital services, cannot be too strongly emphasized. Each community is responsible for this organization within its own limits, and the regional medical heads and their deputies should give assistance in creating efficient units. The care of casualties begins at the site where injury takes place. Smooth and rapid handling and co-ordinated treatment from the time the first-aid party removes the casualty is most important, since this reduces mortality and makes a favorable impression on the morale of the general public. Nothing but constant drilling and training can produce a smooth running organization. A spirit of comradeship and pride in efficiency will develop within the personnel when a sense of purpose and teamwork is attained.

In large metropolitan areas with deputies acting as chief medical officers in the various report centers, the chief medical officer should also appoint a deputy in charge of organizing all the hospitals in his district on a twenty-four hour basis. Also, in the event of severe and continued bombing, casualties should be evacuated from the emergency hospitals to base hospitals in the country. This is not the responsibility of the chief medical officer, he should report his needs to the regional medical head who will provide transportation and hospitalization through the evacuation officer.

lowing assembly at the medical depot and subsequent notice of disaster, the unit proceeds to the site of the incident.

**b First Aid Parties** A first aid party comprises six ARP wardens, assigned to first-aid duty, who operate under the commanding officer of the medical first-aid post. Each must have taken one of the first-aid courses

given by the American Red Cross and should be thoroughly trained as a stretcher bearer; he is equipped with a first-aid kit belt (Appendix B), and the party obtains stretchers and blankets from the medical first-aid post. The party should attach and fill out identification tags (Fig. 5), should give emergency medical care (first aid only) and should either transport the wounded by stretcher to the medical first-aid post or direct the walking to this post or to a casualty station (usually located at the medical depot). A casualty should *not* be taken, sent or directed to an emergency hospital unless it is so ordered by a physician from the medical first-aid post.

*c. Medical First-Aid Posts.* The personnel consists of two physicians, two graduate nurses, and four female and four male volunteers who have had Red Cross first-aid training and who can act as assistants and as stretcher bearers. One of the physicians should be made the commanding officer, with the responsibility of dispatching the first-aid parties to collect casualties, receiving and treating the wounded, and dispatching the ambulances to the emergency hospital.

The medical first-aid post requires at least two rooms, preferably with running water in each. The walking wounded should be directed to one of these rooms (or to the medical depot or other places equipped and staffed to function as casualty stations), and the stretcher cases should be taken to the other. Portable wooden or metal horses should be part of the equipment (kitchen tables, chairs and so forth can be improvised); on these, the stretcher should be placed, so that the patient can be splinted or given further medical treatment without being moved off the stretcher.

A chest (Fig. 6) containing the medical first-aid post supplies, and all other equipment (Appendix C), should be kept in a designated spot, preferably the medical depot, and

these tags are supplied to each medical first-aid post, as well as being in the kit belts of the first-aid parties. If the tag was not put on by the first-aid party, it must be attached and filled out at the first-aid post by the registrar; if only partly filled out, it must be completed. An additional official record must be kept by the registrar of each post, preferably in a *book*; and this must be turned in to the chief medical officer at the end of each tour of duty. The record should be brief but must include everything on the tag and a short account of the treatment, especially the administration of drugs, and of the disposition of the case.

Each medical first-aid post should have a duplicate or, preferably, triplicate personnel, so that service can be maintained on a twenty-four-hour basis, in twelve-hour or eight-hour shifts; even duplicate or triplicate sets of supplies and equipment may be provided.

*d. Medical Depots.* One or more medical depots are located in each report-center area. Fire stations, police stations and school buildings are suitable sites. There, the supplies and equipment of the first-aid parties, medical first-aid posts and casualty stations, for which the chief medical officer is responsible, are stored, and there, the personnel of these units and ambulances assemble in times of emergency. It will also be used by the Red Cross for the storage of its medical supplies. The officers in charge of medical depots need not be physicians—pharmacists or employees of medical-supply houses are quite suitable.

In densely populated areas, this depot may be used as a casualty station for the care of the lightly wounded, since it is desirable not to crowd the medical first-aid posts or the emergency hospitals with such minor cases. Furthermore, portions of the same building or adjacent buildings should serve as an assembly station for the Evacuation Division, and as a base for mobile canteens and a storehouse for the supplies and equipment required by the Red Cross for the clothing, feeding and housing of uninjured but destitute citizens.

Exchange of equipment between first-aid parties and medical first-aid posts will proceed as equipment is used. First-aid parties will go into a demolished area with their stretchers, blankets and first-aid kits. They will evacuate the wounded to the medical first-aid post, leaving the stretchers and blankets. There they will pick up reserve supplies of stretchers and blankets and, if necessary, gauze supplies for their emptied kit belts and will return to the scene of disaster to evacuate other casualties.

Auxiliary medical depots should be established in every emergency hospital for the interchange of stretchers, blankets and splints. When an ambulance evacuates stretcher cases with Keller-Blake or Murray-Jones splints from a medical first-aid post to an emergency hospital, the driver picks up at the hospital an equivalent number of stretchers, blankets and splints and returns to the medical first-aid post. The chief medical officer must see to it that such supplies are adequate at all times in all places and should replenish these supplies from the medical depot.

Although equipment must be exchanged, there should be *no* change in the assignments of medical, nursing and other personnel, other than relief after eight or twelve hours of continuous duty.

*e. Auxiliary Emergency Medical Depots.* The National Pharmaceutical Association and some of the state pharmaceutical associations, including Massachusetts, have offered to provide certain drugstores with supplies for the emergency use of physicians and first-aid-trained ARP wardens. It has been suggested that such stores be designated by

FIGURE 6. Box for Storage of Supplies, Instruments and Drugs of a Medical First-Aid Post.

should be transported by the ambulances when the mobile medical unit is ordered out. Each post should be equipped with at least three powerful electric lanterns operated by dry cells (for example, Red Bird lanterns), as well as with suitable material for blackout.

When the medical first-aid post is established, one member of this unit (preferably one of the female first-aid volunteers) should act as *registrar*. The wounded will enter with identification tags tied on by the first-aid party, on which certain data are to be written;

an appropriate window sign such as Emergency Medical Depot, they will have a cabinet where compress bandages, triangle bandages and supplementary wooden splints are stored.

*f Casualty Stations* In metropolitan areas, the chief medical officer may deem it advisable to establish casualty stations for the treatment of the less seriously wounded. These may be located at the medical depots, as previously mentioned, or at other strategic sites, emergency hospitals should *never* be used for this purpose. As at the medical first aid posts, a record of all casualties must be kept and turned in daily to the chief medical officer.

*g Transportation* Transportation of the personnel and equipment of the first aid parties and medical first aid post to the scene of disaster is provided by passenger cars and ambulances, and that of the seriously wounded from the first aid post to the emergency hospital by ambulances. When ordered by the chief medical officer, the drivers report to the medical depot with their cars. If a sufficient number of ambulances are not available through the Red Cross or otherwise, the chief medical officer must provide for additional vehicles, with drivers. So far as possible, police-department and fire department ambulances should not be used, since they will probably be needed for other emergency purposes. The commanding officer of the medical first aid post is responsible for the evacuation of patients to the emergency hospital. The ambulances should be operated by the shuttle system, whenever possible.

Beach wagons and one ton or one and a half ton panel body delivery trucks may be converted for ambulance use. In fact, any kind of delivery vehicle or small truck on the floor of which can be placed two stretchers will serve the purpose.

Two drivers should be detailed to each ambulance, and both should be trained in first aid care. Members of the Red Cross Motor Corps and women trained by the Women's Civilian Defense School have had such training in addition to experience in convoy duty and driving under black-out conditions.

*h Emergency Hospitals* In each community, the medical committee should organize the existing hospitals for casualty service. This means that the staff physicians, dentists and nurses should be allocated to two twelve hour or three eight hour shifts. Small communities should be so organized, as previously mentioned, that the nearest hospital is available. All hospitals used as emergency hospitals should increase their supplies of medical material and of permanent food, such as canned goods. Such hospitals should also carefully study the black-out regulations outlined in two manuals, *Blackout Information to the General Public* and *Blackout Information, Lighting and Ventilation for Industrial Plants and Commercial and Public Buildings*, compiled by the Protection Division of the Massachusetts Committee on Public Safety, and in a booklet, *Protective Construction Series No. 1 Glass and glass substitutes*, issued by the Office of Civilian Defense, Washington, D. C., and equip themselves for such an event. In the large centers, the hospitals should begin the training of nurses aides, preferably under the new Red Cross system, in which a satisfactory preliminary training can be given to volunteers from the lay public. Once such training has been completed, the volunteer nurses aides should keep in practice by periods of active duty in the hospital every three or four months or by continuous service.

An experienced surgeon should be in charge of the disposition of all casualties brought to the hospital by ambulance.

All emergency hospitals should be equipped with the necessary furnishings for two, preferably three operating rooms for seriously injured cases, with operating teams, anesthesia service and nursing personnel so that at least two, preferably three operations may be carried on at the same time. If an air raid occurs in any sizable community, the emergency hospital is expected to double or triple the personnel so that the operating rooms may be used on continuous twenty four hour service (either twelve hour or eight hour shifts). This service is essential but will vary somewhat with the size and population of the community. In urban areas, it is essential that the hospital have protected operating rooms with independent lighting systems, preferably in the basement, where they will be protected from bomb splinters and broken glass and where they may function undisturbed.

In urban areas all casualties should be prepared for evacuation to a base hospital the next day, if the circumstances warrant.

The emergency hospitals, as previously stated, must have available at the ambulance entrance an adequate supply of stretchers, blankets and splints, to interchange supplies with incoming ambulances. Such supplies should be obtained from the medical depot.

In large and moderately sized hospitals, outpatient department facilities must be made available, on a twenty four hour basis for the less seriously injured ambulatory casualties (walking wounded) who have not been to a medical first aid post. The flow of patients should be arranged on a one way traffic basis so that large numbers can be handled without confusion, and an experienced surgeon should be in charge since many apparently minor injuries may be extensive and severe. Those with minor injuries should be evacuated to their homes, whenever possible, but should receive clinic treatment daily until ready for discharge to full employment or civilian life. In the metropolitan areas special dressing stations may be set up or the casualty stations used for the care of those who are ambulatory.

*Members of permanent hospital staffs should not be used as personnel in medical first aid posts, because in an emergency they will be more necessary at their hospitals.*

All emergency hospitals, on orders from the chief medical officer, should discharge to their homes, to previously designated convalescent homes or to base hospitals as many of their regular patients as possible—this should mean about 50 per cent of the census. Furthermore the emergency hospitals should acquire sufficient cots, blankets, splints, drugs and other medical supplies to provide for 25 per cent more than the average census.

**6 BASE HOSPITALS** As soon as possible after adequate surgical care has been completed, all casualties in emergency hospitals should be evacuated to large hospitals in the country, chiefly sanatoriums and hospitals under state control. This evacuation of patients will be accomplished by truck, bus or train and will be supervised by the regional medical head or a deputy appointed by him.

**7 MEDICAL ASPECTS OF EVACUATION** In any disaster only a portion of the population in the area will be injured, but many others will be rendered homeless and frightened. The latter may need clothing, temporary shelter and an opportunity to reunite their families or to plan for the future, furthermore, serious medical conditions may arise. The medical care of the noninjured civilian population is the responsibility of the Evacuation Division, which has its own medical organization, distinct from the Medical Division but working in close co-

operation with it. At regional and local levels similar liaison should obtain between these two medical groups. Food, clothing and temporary shelter for these refugees will be provided by the American Red Cross.

Evacuation of the civilian population involves more than emergency service at the time of disaster. People living in areas near military reservations or on islands may have to be moved to less dangerous regions; other areas may be within the theater of military operations. In any large-scale preplanned evacuation, preference would have to be given to mothers and children, the aged, the infirm and the handicapped. Such groups would necessarily create special medical problems in areas to which they might be evacuated. Educational, recreational and social-service facilities would have to be provided, together with the appropriate personnel, by arrangement with the Division of Health and Social Service. The organization to meet the various situations and the medical responsibilities entailed are described in bulletins and manuals prepared by the Evacuation Division. Reception areas will be established to which evacuees will be sent. At these points, medical care of the evacuees will be provided by the Evacuation Division until the emergency is over.

8. DECONTAMINATION. The control and care of gassed individuals who are not wounded will be handled by a special unit of the Protection Division. Men who have been instructed in marking out contaminated areas and in the care of burned and gas-contaminated patients will be detailed for this work. Those who wish to study the methods of decontamination in detail should consult the special pamphlet on gas defense that has been issued by the Protection Division.

From the point of view of the Medical Division, it must be clearly understood that nonwounded gassed patients should *not* be routed to emergency hospitals. The commanding officer of the medical first-aid post should send all gas casualties, after whatever emergency surgical care is necessary, to a decontamination center. This will avoid overcrowding the hospitals with people who usually need only a bath and change of clothing, and will prevent further contamination of valuable personnel with gas; furthermore, the hospitals could not possibly handle this type of casualty without considerable addition to personnel and equipment.

9. CARE OF THE DEAD. Proper disposition of the dead is important from the point of view of morale of the general public and of the mobile medical units and emergency hospitals. Arrangements should be made with the local medical examiner for the immediate removal of the dead. The ARP wardens should segregate the dead from the injured, and should send the former, not to a medical first-aid post or to a hospital, but to a center previously designated by the medical examiner, transportation being accomplished by ambulance. So far as possible, the dead should be kept from view. It is a surprisingly favorable commentary on the system in London that few people there have seen many dead casualties, in spite of heavy loss of life.

\* \* \*

#### APPENDIX A. *Data Concerning Report Centers, Medical First-Aid Posts, First-Aid Parties, Ambulances and Medical Depots in a Large City.*

The following is the proposed setup in Boston, with a population of about 840,000.

*Report Centers.* Twelve report centers will be established.

*Medical First-Aid Posts.* On the basis of 1 medical first aid post for each 10,000 inhabitants, there should be approximately 84 posts, or 7 posts attached to each report center.

*First-Aid Parties.* On the basis of 2 first-aid parties for each medical first-aid post, there should be approximately 168 parties, or 14 parties attached to each report center.

*Ambulances.* On the basis of 3 (preferably, 4) ambulances for each mobile medical unit (1 medical first-aid post and 2 first-aid parties), there should be approximately 252 (preferably, 336) ambulances, or 21 (preferably, 28) ambulances serving each report center. (As a matter of fact, this large number of ambulances is unnecessary in such a densely populated region, since it is extremely unlikely that all areas would be hit at any one time and since the exchange of ambulances from one report center to another is easily accomplished.)

*Medical Depots.* Since each report center should have at least 1 medical depot, there will be a minimum of 12 medical depots. The medical depot or depots in each report center might be called on to supply 7 medical first aid posts, 14 first-aid parties and 21 (preferably, 28) ambulances.

#### APPENDIX B. *Contents of Kit Belt for First-Aid Party.*

A first-aid kit belt contains the following:

- 1 pkg. Bandage compresses, 2 in., 4 per pkg.
- 1 pkg. Bandage compresses, 3 in., 2 per pkg.
- 2 pkg. Bandage compresses, 4 in., 1 per pkg.
- 1 yd. Gauze, absorbent
- 1 Bandage, gauze, 4 in.
- 2 Bandages, cravat triangle, nonsterile
- 1 pkg. Adhesive compresses, 1 in., 16 per pkg.
- 2 pkg. Tannic acid jelly
- 1 pr. Scissors
- 1 pr. Tweezers
- 1 Lipstick, red (for marking tourniquet cases)
- 1 Pencil, indelible (for identification tags)
- 10 Tags, identification.

The first six items will be supplied by the American Red Cross; applications should be made to the First Corp Area Emergency Office, 161 Massachusetts Avenue, Boston.

#### APPENDIX C. *Supplies, Instruments, Drugs and Equipment of a Medical First-Aid Post.*

The supplies, instruments, drugs and equipment of a medical first-aid post are as follows:

##### SUPPLIES

- 6 pkg. Red Cross "units," 2 gauze kits and 2 table covers per pkg.
- 2 pkg. Towels, 12 per pkg.
- 2 pkg. Bandages, gauze, 2 in., 12 per pkg.
- 2 pkg. Bandages, gauze, 3 in., 12 per pkg.
- 2 pkg. Slings, 6 per pkg.
- 1 pkg. Binders, scultetus, 4 per pkg.
- 1 roll Tape, adhesive, 1 in., 10 yd.
- 1 roll Tape, adhesive, 2 in., 10 yd.
- 1 box Throat sticks, wood, 10 per box
- 2 Mouth gags, wood
- 12 ft. Rubber tubing (for tourniquets)
- 5 rolls Cotton, absorbent, 1 lb. each
- 1 box Pins, safety
- 24 rolls Sheet wadding, 24 in.
- 4 pr. Gloves, rubber, Sizes 7½ and 8

- 4 Catheters, urethral, No 14 Fr
- 50 Cups, waxed paper
- 12 Splints, brasswood, 30 x 3½ x 3/16 in
- 4 Brushes, nail
- 6 cakes Soap
- 2 boxes Matches
- 1 Lipstick, red
- 1 Pencil, indelible
- 200 Tags identification

## INSTRUMENTS

- 2 Scissors Mayo, curved, 6 in
- 2 Knife handles, Bard-Parker No 3
- 12 Blades, Bard-Parker No 10
- 6 Snaps, straight 5½ in
- 6 Snaps curved, 6¼ in
- 4 pr Forceps, toothed, 6 in
- 2 pr Forceps, smooth, 6 in
- 12 Needles, Keith
- 12 Needles, full curved, Ferguson or Mayo 3½ in curve
- 50 tubes Ties, black silk, sterile (No 4 Gudebord)
- 6 tubes Sutures, catgut, sterile, No 1 plain
- 12 tubes Sutures, catgut, sterile, No 1 chromic
- 2 Shears, bandage, 7½ in
- 2 Syringes, Luer, 2 cc
- 12 Needles, hypodermic, 25 gauge
- 6 Flashlights, pencil type
- 1 Blood pressure apparatus
- 1 Stethoscope
- 1 Airway tube, Connell, large (3¼ x 7/8 x 3 9/16 in)
- 1 Airway tube, Connell, small (2¼ x 3/4 x 3/8 in)
- 2 Retractors
- 1 Tube tracheotomy
- 1 Razor, safety, with 20 blades
- 1 Razor straight
- 1 Stove (No 520, Coleman)
- 3 Lanterns, electric, dry-cell type (Red Bird)
- 2 Batteries, extra (for lanterns)

## DRUGS

- 50 pkg Sulfanilamide, powder, sterilized 4 gm each
  - 50 pkg Sulfathiazole, powder, sterilized 4 gm each
  - 1 qt Alcohol 70 per cent
  - 2 bot Morphine sulfate, sterile solution 20 cc each with rubber-diaphragm stopper (1 cc contains ¼ gr morphine sulfate)
  - 12 amp Nikethamide, 15 cc each
  - 2 pkg Chlorinated lime mixture, dry, in airtight tin, each containing
    - Chlorinated lime (30 per cent chlorine) 200 gm
    - Sodium bicarbonate 200 gm
    - Sodium carbonate, CP, anhydrous 80 gm
- For use, mix a portion of the dry powder in the hands with sufficient water to form a thin cream 4 minutes' rubbing with this cream is equivalent to 20 minutes' scrubbing
- 1 bot Aromatic spirits of ammonia, 2 oz
  - 6 pkg Tannic acid jelly, 2 oz each
  - 6 tubes Vaseline, white, 2 oz each
  - 1 qt Givoline in nonleaded can (for stove)

## EQUIPMENT

- 4 Trays solution, 3 in deep, nested
- 1 Sterilizer, enamel, with cover (to nest with trays)
- 2 Pails galvanized 10 qt
- 2 Sheets rubber 7½ x 25 in

- 2 Aprons, rubberized
- Blackout fabric
- 2 Tables, folding 30 x 30 in
- 2 Horses, wood or metal
- 6 Stretchers
- 12 Blankets
- 6 Splints, leg Keller-Blake
- 6 Splints, arm, Murray-Jones
- 1 Medical first aid post marker

All supplies, instruments and drugs are best packed in a wooden chest with rope handles (Fig 6), although bags of waterproof material or fiber suitcases will suffice.

The first six items of equipment can be packed in a duffle bag, and the remaining items should be placed in the ambulances in the most convenient places.

## BOOK REVIEWS

*Clinical Practice in Infectious Diseases for Students, Practitioners and Medical Officers* By E H R Harnes, MD (Lond), MRCP, DPH With a foreword by W Allen Daley, MD (Lond), FRCP, DPH 8°, cloth, 468 pp, with 31 illustrations and 28 tables Baltimore Williams and Wilkins Company, 1940 \$6.00

This is an up to date, trustworthy manual of the acute infectious diseases. After preliminary considerations of infection and resistance, transmission, serum sickness, general diagnosis and management, and the like, the individual maladies are considered in the usual fashion—definition, cause, clinical picture, pathology, complications, treatment, prevention, if any, and general management from the point of view of public health. The public health laws to which reference is made are, of course, British and not American.

This book will be most useful perhaps to the student brushing up or to the general practitioner venturing so little into these fields that he finds himself growing a bit rusty.

*A Primer for Diabetic Patients. An outline of treatment for diabetes with diet, insulin and protamine zinc insulin including directions and charts for the use of physicians in planning diet prescriptions.* Seventh edition, reset. By Russell M Wilder, MD 12°, cloth, 184 pp, with 11 tables 7 illustrations and 1 plate Philadelphia W B Saunders Company, 1941 \$1.75

The seventh edition of this excellent manual emphasizes the combination of protamine zinc insulin and regular (or crystalline) insulin in one injection. Definite rules for the adjustment of insulin doses are given, which provide for reduction of dose as improvement occurs. While insulin is being used Wilder encourages the patient to permit traces of sugar in the urine at all times, to avoid reactions. Average diets contain not more than 167 gm carbohydrate. Low fat and undernutrition diets are avoided. Directions for the management of coma, hypoglycemia and other complications are included. Both physician and patient will find the book most useful.

*Hydrotherapy in Psychiatric Hospitals* By Rebekah Wright, MD 8°, cloth, 334 pp, with 91 illustrations Boston The Tudor Press, 1940 \$4.00

This book is a revision of *Hydrotherapy in Hospitals for Mental Diseases*, published in 1932 by the same author. Dr Wright has rearranged the text, added descriptions of a few new procedures and inserted more illustrations.

The first part of the book is meant for physicians who prescribe hydrotherapy in psychiatric hospitals. The second part, directed to nurses and hydrotherapists, presents detailed descriptions of technics utilized in applying cold packs, continuous baths, irrigations and other forms of hydrotherapy so frequently made use of in mental hospitals.

The author is director of hydrotherapy for the Massachusetts Department of Mental Health, and physicians working in psychiatric hospitals in Massachusetts have been familiar with her work for a long time. The technics that she describes are standard procedures in the state hospitals.

Physicians interested in utilizing hydrotherapy in the treatment of their patients will be glad to see this revision of Dr. Wright's book.

*Modern Dermatology and Syphilology.* By S. William Becker, M.D., and Maximilian E. Obermayer, M.D. 4°, cloth, 871 pp., 461 illustrations and 32 colored plates. Philadelphia: J. B. Lippincott Company, 1940. \$12.00.

Several unusual and acceptable features appear in this book. In the first place, the functional aspects of skin disease are emphasized. Secondly, it is less encyclopediac than most of the textbooks on dermatology, unusual diseases and tropical diseases being hardly mentioned. On the other hand, more space has been allotted to the commoner and more important dermatoses. The term "eczema" is not used, but there is a thorough discussion of the effects of external agents on the skin under the headings of "Toxic Dermatoses," and of the effects of internal factors and of certain functional diseases of the skin under the title "Neurodermatoses." In the latter group are included the following: idiopathic pruritus of various types, neurotic excoriations, neurodermatitis, dyshidrosis, chronic urticaria and alopecia areata. The authors have made a real contribution to dermatology by their investigations of this group and in frequently indicating their relation to other functional diseases, such as colitis, rhinitis and migraine. In fact, the general relations of skin disease to the bodily economy are emphasized throughout the book, in accordance with the authors' statement, "Its diseases are reflected in changes in other parts of the organism and it often mirrors internal diseases."

The chapter on pigmentary diseases is another outstanding contribution. Becker has done much investigative work with pigment, and the classification of pigmentations at the beginning of the chapter and the discussion of these diseases present the opinion of an authority on the subject.

Each chapter contains a paragraph of explanation that discusses the relation of the subject of the chapter to other subjects or brings out points of general interest concerning the subject under consideration.

Therapy is discussed in the introductory chapter, with a formulary and explanations of individual therapeutic procedures. In the discussion of the therapy of an individual dermatosis, the lists of procedures detailed by previous authors are often less complete than those in the usual textbooks. However, the authors discuss treatment from their experience with patients at the University of Chicago clinics. In the management of the functional dermatoses, their method is given in considerable detail; this has been of decidedly practical value, and should be helpful to the average physician in the handling of such cases. The discussion of syphilis is especially full and reviews the general manifestations of the late type and their therapy in more detail than the average dermatologic text.

Excellent photographs supplement the text, and of particular value are the color plates, which are indispen-

sable in the presentation of skin manifestations. Of value also are the tables on cutaneous lesions, lists of etiologically important plants, weeds and trees, and lists of patch-test dilutions and drugs.

Taken altogether, the title is well chosen, and a modern viewpoint of dermatology is well presented, particularly in the four introductory chapters on the neurodermatoses, the pigmentary diseases, therapeutic methods and syphilis.

*Electrocardiography, Including an Atlas of Electrocardiograms.* By Louis N. Katz, M.D. 4°, cloth, 580 pp., with 420 engravings, including 806 electrocardiograms. Philadelphia: Lea and Febiger, 1941. \$10.00.

*Exercises in Electrocardiographic Interpretation.* By Louis N. Katz, M.D. 4°, cloth, 222 pp., with 128 engravings containing 189 electrocardiograms. Philadelphia: Lea and Febiger, 1941. \$5.00.

These two volumes supplement each other, the latter furnishing illustrations for practice in applying the principles of the former. The textbook itself, however, is lavishly illustrated, and it amply confirms the claim that it contains "an atlas of electrocardiograms." The combination of these books really constitutes a complete course of clinical electrocardiography and justifies their high cost.

The plan of the larger volume consists of a division into three main sections, with sixteen chapters and a separate bibliography for each section. The sections are, "Theory of Electrocardiography," "Systematic Description of the Electrocardiographic Contour" and "Systematic Description of the Electrocardiogram in the Arrhythmias."

The first section gives an excellent background in the bioelectric phenomena involved in electrocardiography. Because of his own investigations, the author has deserted to a considerable degree the principle of vector analysis of these phenomena. This remains disputed ground but alters little the clinical aspects of the subject. Anatomy and physiology are adequately considered, and the illustrations are excellent. The place of the electrocardiogram in clinical practice is defined, and one sentence might be framed in the conscience of each practitioner of this art "In short, the electrocardiograph is not a tool for the unscrupulous, or a plaything for the erudite, nor is it an instrument of precision which replaces the ordinary clinical examination."

The second and third sections may also be approved without important reservations. The precepts are sound, and the examples carefully selected. Clinical relations, electrocardiographic findings in various diseases and the influence of digitalis are emphasized, as is the therapy of the various arrhythmias. A preponderant space is properly given to coronary heart disease.

The so-called "exercises" consist of 90 unknown cases with electrocardiograms from which interpretations are made and correlated with the clinical data. When helpful in the analysis, serial tracings on the same patient are shown. In each case, the electrocardiogram is illustrated and studied under the following headings: description, interpretation, clinical story and correlation. Preceding the unknown cases is a short section on the technique of the approach to an electrocardiogram, and the steps necessary in its analysis. For this reason alone, the volume is useful to one with some knowledge of the subject, particularly for a review of his own interpretations in the light of the most recent cardiovascular knowledge.

The reviewer recommends the work wholeheartedly. It demonstrates, beyond question, not only that electrocardiography is of great practical importance, but also that it is a lively and developing science.

## RESULTS OF FIFTEEN YEARS OF THE CANCER-CONTROL PROGRAM IN MASSACHUSETTS\*

HERBERT L. LOMBARD, M.D.,<sup>1</sup> AND FRANCES A. MACDONALD, A.B.<sup>†</sup>

BOSTON

FIFTEEN years ago, the Commonwealth of Massachusetts inaugurated a cancer control program with three objectives: the prevention of cancer, the early recognition and treatment of the disease, and the increase of existing knowledge by the scientific analysis of every fact and record available. To attain these objectives, diagnostic cancer clinics, treatment centers, research and education were necessary. The care and treatment of the incurable case might have been considered for humanitarian reasons, but this activity did not come logically under the heading of cancer control. The Massachusetts Cancer Program from its inception has comprised five parts: statistical research, tumor diagnosis service, hospitalization, diagnostic clinics and education. The evolution of the program has been presented in the literature. An appraisal of the results of cancer control in Massachusetts, together with indications of future trends, is given in this report.

The evaluation of a program of cancer control differs markedly from that of one directed against a communicable disease. Within a few days in the presence of a smallpox epidemic, the results of vaccination are apparent. Even with rabies, the time element is short compared with that of cancer, in which years may elapse between the beginnings of a chronic irritation and a subsequent cancer. Neither measures directed at the prevention of cancer through the elimination of chronic irritations nor those attempting effective therapy may be evaluated until after an interval of years.

The best criterion of measurement is the adjusted death rate. Other criteria are the various delays before therapy, the increased interest of the medical profession and the laity, and the attend-

ance at clinic and hospital. The period in which the Massachusetts Cancer Program has been functioning has been long enough to warrant appraisals by all these methods.

In the state aided clinics, the delay between the first recognized symptoms of the disease and the time the patient presents himself to a physician is one measure of the effectiveness of education of the laity. In the early years of the cancer program, this delay averaged 65 months. Between 1936 and 1939, it was 53 months, and in 1940, 46 months. A similar estimate of the effectiveness of education is the percentage of patients with cancer who go to their physicians within the first month of recognized symptoms. In 1940, 21 per cent of the clinic cancer patients went to their physicians within the first month of their symptoms, as compared with 15 per cent in the early years of the program. A second period of delay is that between consulting the first physician and visiting the cancer clinic. This delay, which may be attributed to either physician or patient, or both, has been decreasing rapidly and is now about half what it was in the early years of the clinics. The third delay is between presentation at the clinic and the institution of treatment. The social workers in the clinics have helped to reduce this delay. About two thirds of the patients are treated within one week, and over 90 per cent within one month of first clinic visit. There has also been considerable curtailment in this period of delay since the early years of the clinic.

The sum total of these delays, however, amounts to more than one month in the majority of cancer cases in the clinics. Only a small percentage of patients receive therapy within one month of the first symptoms. In the early years of the clinics, the percentage being treated in one month was 31; in 1939, it had increased to 58. The shortening of all these intervals of delay points toward

<sup>†</sup>American Division of Adult Hygiene Massachusetts Department of Public Health.

improvement in the cancer situation in Massachusetts (Table 1).

Although the adjusted cancer death rate is used for most comparisons, the actual number of deaths is of importance from an administrative standpoint,

TABLE 1. *Annual Percentage Change.*

Annual percentage reduction in delay of cancer patients before going to first physician	39
Annual percentage reduction in delay of cancer patients before attending clinic	44
Annual percentage reduction in delay of cancer patients between clinic and treatment	38
Annual percentage increase of number of physicians referring patients to clinic	105
Annual percentage increase in cancer deaths	23
Annual percentage increase of specimens sent to Tumor Diagnosis Service	45
Annual percentage increase of clinic admissions of cancer patients	110
Annual percentage increase of general-hospital admissions of cancer patients	47

since measures directed toward care and treatment depend on numbers rather than rates. During the period of the Massachusetts Cancer Program, the actual number of deaths has increased annually by about 2 per cent. During this same period, the clinic attendance of cancer patients has increased annually about 11 per cent, the number of specimens sent to the diagnostic laboratories about 4.5 per cent, and the admissions to general hospitals about 5 per cent. This latter figure is of particular significance inasmuch as additional facilities for cancer patients at the Pondville, Westfield and Palmer Memorial hospitals have been made available during the period.

Additional evidence is obtained from samples from the death records of 1932 and 1940. In 1932, 31.1 per cent of the fatal cases had never been treated in a cancer hospital for the disease. In 1940, this figure had been reduced to 15.8 per cent. Hospitalization for cancer is increasing far more rapidly than the cases of the disease.

Although the attendance of new cancer patients at the state-aided clinics has increased five times as fast as the deaths, only about 8 per cent of the cancer population are seen in the clinics. The other 92 per cent make use of other facilities for diagnosis.

The effect of the clinics, however, is of far greater consequence than the actual number of cases seen. Each clinic acts as a center of cancer interest for the surrounding territory, and the consciousness of cancer of both the public and the profession is enhanced. Moreover, teaching clinics furnish postgraduate instruction for the medical profession. Between sixty and seventy of these clinics are held each year, and over 1300 physicians attend them. Although the cancer

clinics admit about 1800 new cancer patients each year, the total attendance comprising new and old cancer patients and persons who are found to be free of malignant lesions numbers approximately 21,000.

Since the opening of the cancer clinics, approximately 14,000 patients with cancer have attended the clinics. Forty per cent of these are still alive. At the end of ten years after coming to the clinic, 47.0 per cent of the patients with cancer of the skin were alive, 23.3 per cent with cancer of the mouth, 21.6 per cent with cancer of the uterus, and 15.6 per cent with cancer of the breast. Inasmuch as ten years after clinic admission the dying-off curve for the clinic patients is almost identical with that of the Massachusetts population, most of these cases may be considered to be cured.

The changing attitude of the public and the profession toward the cancer program may not be considered an actual measurement of accomplishment, but it does seem to be an indication of existing trends. During the period of the program, questionnaires have been sent to the physicians of the State several times requesting frank comments on the program. In the first few years, there were a large number of adverse comments coupled with constructive criticism. The latest questionnaire, answered by about 1500 physicians, revealed only one adverse comment. Some of the physicians who did not answer were doubtless not in sympathy with the program, but a change so great as this indicates the change in professional opinion. The physicians are also giving their time to address meetings of the co-operative cancer-control committees. In Boston, it was found that two thirds of the doctors were willing to speak, whereas in the smaller communities the percentage is often 100. Steadily increasing numbers of physicians are referring patients to the cancer clinics. In 1940, physicians referred 80.8 per cent of the patients to the clinics. This is in sharp contrast with the 20.1 per cent who were referred in the first year of the program. The number of physicians making use of the tumor diagnosis service has increased. Between 1927 and 1935, there were 421 physicians who used this service, and in 1940 there were 798. In the same period, the number of specimens increased from 2813 to 3907. The increase in the number of doctors using this service has been greater than the increase in the number of specimens. Monthly bulletins, containing excerpts from the cancer literature, and the volume *Cancer: A manual for practitioners*, which have been furnished by the department to physicians in the State, have been

well received, as evidenced by the large number of letters received from the profession.

The public has shown a remarkable change in attitude. In the early days of the program, it was rather difficult to obtain an audience of any size if cancer was the subject under discussion. Meetings were arranged, with talks scheduled on chronic disease and adult hygiene, simply to cover the subject of cancer. Today, the members of the co-operative cancer control committees number over 10,000 and usually have little difficulty in arranging for cancer meetings.

Real comparisons of the prevalence of disease between communities and between different intervals in the same community cannot be revealed by crude death rates, if the age-sex composition of the

bly indicates improvement in diagnosis of the primary site of cancer, and that cases formerly called stomach and liver are now being assigned to other locations.

Inasmuch as a decided drop in the cancer rate among females began in 1935 in Massachusetts, additional computations were made of the adjusted rates of Massachusetts from 1900 to 1939, compared with the eleven states that comprised the Registration Area of 1900. Between 1900 and 1925, the trend for males was upward in both Massachusetts and the Registration Area, and the annual percentage increase was only slightly higher in the latter than in the former. Among females during the same period, the rates for Massachusetts and the Registration Area were both up-

states varies and the disease has a predilection for certain age groups. A common base of comparison mathematically figured, by adjusting the age distributions by states to a standard population, makes possible a more accurate appraisal. Gover's<sup>1-3</sup> comprehensive study of cancer mortality in the United States shows that great differences in adjusted rates occur between the different sections of the country, and the trends of these rates also differ. With Gover's method of comparison and some of her calculations, Table 2 was constructed. This shows the comparison between Massachusetts, the Registration Area of 1920, which included thirty-eight states, and northeast United States, which includes Massachusetts and eleven other states. The average annual percentage change in the rate of mortality from total cancer, from cancer of the peritoneum, intestines and rectum, from cancer of the breast, from cancer of the female genitals and from cancer of other organs was much less in Massachusetts. There was not much difference between Massachusetts and the Registration Area in cancer of the buccal cavity, in cancer of the skin, and in cancer of the stomach and liver. The decrease shown in cancer of the stomach and liver proba-

ward, but to a lesser degree than among males, and both annual percentage increases were almost identical. In the period of the Massachusetts Cancer Program, 1926-1939, the males in Massachu-

setts had a much lower annual percentage increase than the males in the Registration Area, whereas the females in Massachusetts had a 0.2 per cent drop, contrasted with an 0.7 per cent rise in the Registration Area (Table 3).

\* \* \*

This summarizes the accomplishments in cancer control in Massachusetts during the last fifteen

years. One cannot postulate that all the improvement has been due to the Massachusetts Cancer Program. The American Society for the Control of Cancer has worked for over a quarter of a century. The American College of Surgeons has been extremely active, and in the last few years the federal government has inaugurated an extensive cancer program. There may even be forces at work of a biologic nature of which we have no knowledge. However, it seems reasonable to assume that a part of this improvement is due to the constructive efforts of over 7000 physicians in Massachusetts, of the hospitals of this state, of the members of the co-operative cancer-control committees and of the Massachusetts Department of Public Health, which together constitute the Massachusetts Cancer Program.

## THE NATIONAL PHYSICIANS' COMMITTEE\*

STANLEY B. WELD, M.D.†

HARTFORD, CONNECTICUT

AMERICAN medicine no longer enjoys the inviolable right to carry on undisturbed its program of medical care. Although it still commands the respect of its patients, it does not command the unchallenged obeisance of the nineteenth century. This is as it should be. Vast and far-reaching changes are taking place within the social economy of the Nation. Medicine, heretofore considered a profession but now designated by some as a trade, should not expect to escape. One has but to review the accomplishments in the field of medicine alone to realize how rapidly progress has taken place. In one hundred and fifty years, life expectancy in the United States has been raised from thirty-five to sixty-two years, almost 100 per cent. During this same period, smallpox has been robbed of its terror, diphtheria has been conquered, and typhoid fever, tuberculosis, diabetes and a score of lesser ailments have been subjected to control. Today, a child born into an average American home has the prospect of living more than ten years longer than a child born into a similar home in any other great nation of the world. During 1938, American medicine gave to the United States the most favorable

health record of its one hundred and fifty years' history. In this same year, the Nation had the highest general level of health and the lowest death rate ever known in this country or for any comparable number of people anywhere in the world.

The social life of the Nation has undergone a change. On the one hand, widespread unemployment, low farm income and the continuation of conditions of general depression have made it difficult for an ever-increasing number of people to pay for the best medical service and proper hospitalization out of earnings. Concomitant with these conditions, the cost of medical care has increased, owing to many factors involved — not the least of which is the increasing complexity of diagnostic aids. There is at the same time a worldwide trend toward governmental paternalism and the false, suicidal doctrine that the "state" can provide a service and a security that the people cannot otherwise obtain. Most physicians are familiar with families in which the breadwinner, rather than accept a task not to his liking, goes on relief. How this affects the practice of medicine has been too well learned by many a conscientious physician.

Being socially minded, the government at Washington in recent years has attempted to brush

\*Presented at the annual meeting of the New Hampshire Medical Society, Manchester, May 14, 1941.

†Editor-in-chief, *Connecticut State Medical Journal*.

aside the time-worn methods of medical practice, and suggests to the medical profession that it is time for federal control in this field, as in so many others. The Wagner Health Bill was introduced into the Seventy-Sixth Congress, and a health conference was summoned by President Roosevelt. A federal health survey, implemented by the WPA, purported to show the shortcomings of medical care in the Nation—on the heels of a year with the best health record in history! We live in an age of propaganda. This strong arm of the government was drafted to shake the confidence of the public in its physicians as a class. Compulsory health insurance loomed on the political horizon in the last Congress. Its supporters pointed to England, to Germany, to Denmark, to Sweden and to New Zealand as examples of successful compulsory health-insurance programs, making comparisons where comparisons were not only odious but impossible. And riding high on the wave of the whole program of social security, which as yet has a long way to go to demonstrate real security, medical care seemed about to become a political football, kicked off from midfield by its two largest groups of supporters, professors of sociology and economics and well-meaning but misled social workers.

It is true that organized medicine was slow to see the handwriting on the wall. It took small groups in California, in Michigan and in Washington to point the way to more modern methods of better medical care. The physician of the early twentieth century, like his ancestor of the nineteenth, gave little thought to social evolutionary changes in his neighborhood. He was content to go on his daily rounds, caring for all who sought his aid, receiving remuneration where the family exchequer permitted such payment, and caring for the remaining large group, with no reward but the satisfaction of serving his fellow man. He was proud of his labors, worthy of his hire, and gave little if any thought to the discussion of state medicine. An individualist, he saw no reason for relinquishing his claim on his patients so long as they claimed him.

Then, suddenly, the earthquake came, shaking the very foundations beneath him. Assistant Attorney General Arnold secured an indictment against the medical profession for practicing in restraint of trade. It is but fair to recall that the Committee on the Costs of Medical Care in its majority report had advocated group practice of medicine as an aid in extending medical care to a greater number of people. It is also but fair to recognize the efforts of certain groups in this country to establish plans for medical care, based on varying schemes—some good, some bad. But

when the federal government entered the field in open attack against the profession, it failed entirely to realize that the extension of medical care in quantity must include a certain standard of quality to be acceptable to the medical profession.

In November, 1939, the National Physicians' Committee was formed, because it was recognized that for the past twenty-five years there had been evident a trend in political thinking and legislation affecting medicine, medical practice and health. This trend resulted directly in the introduction of the Wagner Health Bill. In May, 1939, the House of Delegates of the American Medical Association had opposed the Wagner Health Bill. Various groups and interests opposing this legislation came to the conclusions that there was real danger in legislation that would result in harmful, revolutionary changes in the system of medicine; that there was a real problem to be solved in connection with the distribution of medical service and hospital facilities; and that the public was uninformed or misinformed about the aims, objects, methods and achievements of American medicine. A group of twelve physicians formed the National Physicians' Committee for the Extension of Medical Service, a nonprofit, nonpolitical organization devoted to maintaining ethical and scientific standards and extending medical service to all the people, and to familiarizing the American public with the facts concerning these methods and achievements.

The American Medical Association has been criticized as reactionary, narrow and obstructive in its actions. Perhaps it has been, but never has it permitted a lowering of the standards of medical care. The association has also been criticized for not carrying on the work now being done by the National Physicians' Committee. It could not. The American Medical Association cannot change its policies on the basis of expediency, or adapt itself to meet emergencies in a short enough time to be effectual. It is exempt from income and social-security taxation as a scientific, educational body, and therefore cannot engage in a campaign within the political gates at Washington. There are many lay groups interested in the solution of these problems from whom the American Medical Association could not expect support.

What has the National Physicians' Committee accomplished to date? First, it has bent its energies on conveying to the public a few factors of such dramatic value that a continuation of the operation would make possible some concept of American medicine's progress and achievements. Let me illustrate how such small beginnings can develop.

In 1939, the Life Saver Company distributed billions of Life Saver candies. This firm started from scratch in a small Bronx garret in 1913 and, through continuous sales effort, built this relatively unimportant item into a total distribution, through chain stores, 800 wholesalers and more than 300,000 retail outlets, of \$4,000,000. Incidentally, E. S. Noble, who did this job and confined his efforts to it, became the first assistant to the Secretary of Commerce. There is practically not a cigar-store or a drugstore counter that does not feature these little candies; there is not a twelve-year-old boy in the United States who does not know what a Life Saver is.

The Wrigley setup is an identical one. The Wrigley Company started from scratch and began selling a not quite respectable commodity. They began fighting the schoolteachers because the children took gum out of their mouths and stuck it under the seats, and the ministers because the undersides of the pews became lined with chewing gum. Ultimately, they imported chicle by the carload and sugar by the boatload until, in 1939, the Wrigley Company grossed \$34,900,000.

The National Physicians' Committee, also starting from scratch, began its effort to inform and educate the public with two *Saturday Evening Post* two-page advertisements that cost \$43,000, with additional costs for art and engraving that brought the total to nearly \$50,000. Industrial firms put up the money to cover the entire cost of these two advertisements. They appeared on June 22 and July 13, 1940.

More important than this was a series of full-page advertisements that appeared from coast to coast in important newspapers. These were patterned after the *Saturday Evening Post* advertisements. This barrage resulted in a statement from Mr. Willkie committing himself to the cause of independent medicine, and a public statement of policy from Mr. Roosevelt prior to his election. All of us are now familiar with Mr. Roosevelt's message at the dedication of the Health Institute in Bethesda, Maryland, when he expressed for the government no intentions of socializing medical practice and lauded the personal relation between doctor and patient that now exists. This, together with the promise to discuss with organized medicine all future legislation affecting the practice of medicine, should at least indicate that concerted effort on our part can bring results.

Following the publicity in the *Saturday Evening Post* and in newspapers from coast to coast, since January 1 there has gone out from the office of the National Physicians' Committee in Chi-

cago a weekly editorial service to more than 12,000 weekly and foreign-language newspapers in the United States. These releases are informative and educational, and should help to correct false impressions of American medicine gained by the public. Very few of these have been published in New Hampshire and Connecticut, but newspaper clippings from publications in February and March indicate 10 to 15 per cent actual publication. This editorial service is still in operation.

On April 4, a federal jury in Washington found the American Medical Association guilty of a "criminal conspiracy to restrain trade." The jury exonerated five officials of the association and fourteen distinguished physicians of the District of Columbia, at the same time convicting the American Medical Association and the Medical Society of the District of Columbia. The verdict is without sense or substance or meaning. Certain basic principles, which in their establishment involved no legal authority, have been challenged. To relinquish them would mean that laymen or lay organizations would have a legal right to provide medical service, that qualified doctors of medicine could no longer determine or influence the qualifications of hospital staffs and physicians with courtesy privileges, and that doctors of medicine would be denied the right to determine or significantly influence the educational standards for medical students, and the nature and quality of intern training. Should this come to pass, the quality and standards of medical service would be placed in jeopardy, and an army of quacks would compete in the open market for the patronage of the ailing and the sick. This decision will be appealed, if necessary, to the Supreme Court of the United States. In the meantime, the public must be informed and made aware of its vital interest in this issue. To this task, the National Physicians' Committee has set itself.

In certain states of the Union, notably California, Michigan, New York, New Jersey and Texas, attempts are being made to provide state-wide service on a prepayment basis under medical-association auspices. The Wisconsin and Minnesota legislatures have passed enabling acts making possible the extension of such a service. Since January 1, 1941, two state societies—Ohio and Tennessee—have sponsored similar legislation. It is this sort of effort that must be encouraged; otherwise the public will be led along the road to compulsory health insurance as outlined in such acts as the Wagner Health Bill and the Epstein Bill.

The program of educating the public concerning a true knowledge of the facts of American med-

icine entails considerable expense. Let us see how the plan was worked out in Houston, Texas. The president of the local medical society appointed a chairman of a committee to co-operate with the National Physicians' Committee. The Houston Medical Society has a membership of approximately 400 physicians. Ten members were selected for the committee. The names, addresses and telephone numbers of all the members were placed on 400 cards, which were divided among the ten committee members. Each member of the committee reached by telephone the physicians assigned to him, explained the nature of the work that had been undertaken by the National Physicians' Committee, and asked them to contribute to the extent that they could without undue sacrifice. Ten dollars was suggested as a reasonable average amount. The president of the society wrote a letter to all the members urging them to co-operate. The committee met each week for a short period until the entire membership had been canvassed. Under the date of November 4, the chair-

man of the committee mailed his check in the amount of \$2,313.50 to the National Physicians' Committee. This plan was effective; it resulted in great good to the members of the Houston Medical Society and can be adapted to any society.

American medicine has been called on to aid in national defense by manning the selective-service medical boards, and by supplying physicians to the Army and the Navy. In addition, Britain has called for 1000 physicians to help fill gaps in its defense program. American medicine is faced with the possibility of drastic changes in its structure. We must not permit the quality of medical service to suffer. The National Physicians' Committee has set itself the task of securing public approval of the standards set up by American medicine and endorsement of only those changes that shall eventuate in improved medical care. The accomplishment of this purpose necessitates the understanding, co-operation and financial support of every county medical society and of the rank and file of the profession.

## THE VALUE OF AUSCULTATION OF THE ABDOMEN IN INTESTINAL OBSTRUCTION

NEIL C. STEVENS, M.D.

WALPOLE, NEW HAMPSHIRE

**A**USCULTATION of the abdomen is a valuable aid in diagnosis of a number of functional and organic conditions of the stomach and intestinal tract. It is particularly useful in cases of intestinal obstruction and acute appendicitis, and four cases of the former condition are cited to illustrate its use.

### CASE REPORTS

**CASE 1.** A 60-year-old farmer complained of severe, cramplike pains in the abdomen. The pain had begun at 4 a.m., waking him out of his sleep, and had continued with increasing severity until examination at 11:30 a.m. The pain was intermittent in character. The patient had vomited twice and had taken an enema, without result. His digestion had always been good; his bowel movements had been regular.

With the exception of the abdomen, physical examination was negative. The abdomen was not distended, although there was a suggestion of rigidity in both lower quadrants. There was marked tenderness at the umbilicus, which was also the area of the maximum intensity of the pain. The temperature was 99°F., and the pulse 85. On auscultation of the abdomen, peristalsis was intermittent. The sounds coincided with the intermittent attacks of pain. The abdomen was completely silent for intervals as long as 2½ minutes. The sounds were rather faint and lasted

not longer than 10 seconds. The spasms of pain were severer than the sounds seemed to indicate. From the character of the sounds and of the pain and from the silent intervals, a diagnosis of intestinal obstruction was made. His immediate removal to the hospital was advised.

On admission to the hospital 2 hours later, the symptoms had not changed appreciably. The white-cell count was 14,000, with 85 per cent polymorphonuclears.

At operation, a volvulus of the middle third of the ileum was found, involving about 20 cm. of the intestine, which was purple in color. Both visible and tactile pulsation of the mesenteric arteries and their branches was evident, and nothing was done except to relieve the obstruction. The patient made an uneventful recovery.

**Comment.** In this case, the onset of pain was at 4 a.m. Operation was performed at 1:30 p.m., an interval of 9½ hours. Peristalsis was present, though faint and infrequent up to the time of operation. The section of the intestine involved was still viable.

**CASE 2.** A 51-year-old farmer began to have pain in the right lower quadrant of the abdomen at about 5 p.m. It came on after finishing a hard day's work in the fields. The pain was colicky to begin with, later on becoming constant. As time went on, it increased in severity. A physician told the patient that he was having an attack of indigestion and gave him some "medicine." The pain persisted

all night, and the patient vomited twice. I saw him the next morning.

Physical examination showed a thin, wiry man who was apparently suffering a good deal of pain. He did not look particularly ill. The temperature was 99.5°, and the pulse 88. The abdomen was not distended, and there was no rigidity. There was considerable tenderness in the right lower quadrant in the region of an old appendectomy scar—the appendix had been removed 6 years before. Peristaltic sounds were present but faint and infrequent.

Because the appendix had been removed and there was no distention or rigidity, I considered it safe to wait until afternoon before deciding what should be done. His wife was told to give him an enema.

At 4 p.m., his condition was much worse, although the pain was not quite so severe. The face was flushed, the respirations were increased, the temperature was 101°F., and the pulse was 100. Peristalsis was entirely absent. The abdomen was distended, and there was extreme tenderness in the right lower quadrant. The patient was taken to the hospital, where an immediate operation was performed.

On opening of the abdomen, there was an outpouring of dark-colored fluid. An area of the ileum, 25 cm. in length, just proximal to the cecum was black. There was a thick band of adhesions originating at the stump of the appendix and attached at its other end to the mesentery of the lower end of the ileum. The devitalized loop of intestine was resected, and an anastomosis was done. The patient died the following day.

*Comment.* This patient was seen 5 years ago, when the value of auscultation of the abdomen was not appreciated in cases of intestinal obstruction. The delay of 8 hours in sending the patient to the hospital was due to the fact that he did not present the cardinal signs of intestinal obstruction. Experience now shows that when the typical signs of obstruction, such as distention, fecal vomiting and a rise in temperature and pulse rate, become evident, it is often too late to save the patient. In this case, it should have been appreciated that the character of the peristalsis indicated advanced obstruction with beginning peritonitis. The sounds were faint and infrequent, a finding that is characteristic of the last stage of viability of the intestine. If the patient had been operated on at that time, he might have survived. Eight hours later the condition was hopeless.

**CASE 3.** A 43-year-old woman complained of abdominal pain. She had been in good health until 2 years previously, when she was operated on for an ovarian cyst. Following this operation, her health had been good until 2 months before I saw her, when she began to complain of vague abdominal pain. One month later, the pain became localized in the left lower quadrant. Three weeks later, the pain increased in severity, and the patient noticed a mass in the left lower quadrant. Three days before I saw her, the mass increased in size, together with an increase in pain and tenderness. On the previous day, the patient had vomited and had been unable to retain anything on her stomach.

Examination showed a long linear scar, 9 cm. in length, extending downward from the navel. The abdomen was greatly distended. A mass, the size of a grapefruit, was palpated in the left lower quadrant. It was extremely tender. Active peristalsis was audible over this mass and sounded close to the ear. The diagnosis of intestinal obstruction was made, and the patient was removed to the hospital.

At operation, many closely matted loops of intestine were found just beneath the abdominal wall and outside the

peritoneum. A rent in the peritoneum, about 8.0 cm. in length and corresponding to the old scar through which the intestines had emerged, was found. The intestines were not badly discolored, and seemed viable. The adhesions were separated, and the tear in the peritoneum was sutured. The patient died on the 3rd day after operation.

*Comment.* In this case, death was probably due to the length of the operation (2 hours), which was occasioned by the attempt to break up innumerable adhesions. At the time of examination, there was some question concerning the nature of the mass, but following auscultation, a definite diagnosis of intestinal obstruction was made.

**CASE 4.** A 37-year-old farmer was seen at the office. He complained of cramplike pains in the abdomen of 2 weeks' duration. For 3 days previously, they had been increasing in severity. His appetite had been poor; he had lost weight and strength.

On physical examination, the abdomen was soft; there was no distention or rigidity; no masses were felt; there was slight tenderness in the left lower quadrant, where most of the pain was located. Peristalsis was active and loud. Rectal examination was negative. The white-cell count was 11,000, with 65 per cent polymorphonuclears.

There did not seem to be any acute condition at the time. The patient was given phenobarbital to quiet down the peristalsis and told to go home and take an enema that evening and the following morning.

The next morning, his wife called up to say that he had had a very uncomfortable night, with a great deal of pain. The enemas had been unsuccessful. He had not vomited, and the temperature was normal. Physical examination was essentially the same as the night before, except that there was complete absence of peristalsis. At intervals over a period of an hour, no sounds were audible. There was no distention, no rigidity and no more tenderness than there had been the previous afternoon.

Because of complete loss of peristaltic sounds, the patient was sent to the hospital with a tentative diagnosis of intestinal obstruction. A surgical consultant saw him soon after arrival and noted no indications of an acute abdomen. The diagnosis was intestinal gripe, and the administration of salts was advised. The patient felt quite well during the afternoon, but had a very bad night. A quarter of a grain of morphine was necessary to stop the pain. The following morning, I saw the patient again, with the surgeon and two other physicians. They agreed that he did not have an acute abdomen and advised keeping him under observation. The blood count, temperature and pulse rate were normal. The tongue was coated. The abdomen was soft; there was no rigidity and only a slight degree of tenderness in the midline below the navel. However, at this time there was slight distention in the suprapubic region. The peristaltic sounds were completely absent.

During the afternoon, the patient complained of a great deal of pain. Toward evening, distention of the abdomen became marked. The temperature was 100°F., and the pulse 105. The peristaltic sounds were completely absent. The face became flushed and drawn. The consulting surgeon was again called and was convinced that there must be some trouble in the abdomen.

At operation, a mass was palpated in the descending colon about the size of a small orange, and proximal to the mass, about 46 cm. of intestine was distended and black. The patient's condition was so poor that nothing more than an enterostomy was attempted; he died the following afternoon.

*Comment* My diagnosis in this case was based on the presence of hypermotility at the first examination, and complete absence of peristalsis noted 14 hours later. Until 3 or 4 hours before operation, it was the only positive physical sign. It preceded the first rise in temperature to 99.5°F by 12 hours. It preceded distention of the abdomen by 36 hours. Neither the pulse rate and blood count—the white cell count just before operation was 10,000, with 77 per cent polymorphonuclears—nor any other physical finding was indicative of a serious abdominal condition.

At the beginning of intestinal obstruction, peristalsis is almost continuous, loud and usually high pitched. The bowel, which is not yet devitalized, is making an effort to overcome the obstruction. A few hours later, peristalsis is still active, but fainter. The musculature of the bowel is becoming fatigued and does not respond so strongly to stimuli. After twelve hours, peristalsis is considerably diminished, and becomes intermittent with intervals of sometimes two minutes between the sounds. By this time, not only is the bowel greatly fatigued, but there is probably a beginning peritonitis, owing to interference with the circulation and the production of toxins, which invade the visceral peritoneum through the damaged wall of the bowel. The last stage, and the one in which the patient most frequently arrives at the hospital, is that of beginning distention, frequent vomiting, and complete cessation of peristalsis; at operation, a section of the bowel is found to be gangrenous.

My experience leads me to believe that, so long as peristaltic sounds are heard, the bowel is not completely devitalized and that the chance for recovery following operation is very good. The

more active the peristalsis preceding operation, the better the chances for recovery. After some experience in auscultation, one can predict with considerable accuracy the condition and color of the bowel that will be found at operation. If peristalsis is active and loud, the section of the bowel involved will be congested and red or pink. If the peristalsis is faint and intermittent, the bowel will be purple. If peristalsis is entirely absent, the bowel will be black. In all but the last stage, the circulation can probably be restored if the obstruction is relieved.

Cessation of peristalsis seems to depend on infection or irritation of the peritoneum. It most commonly occurs in such conditions as intestinal obstruction, acute appendicitis (before and at the time of rupture) and rupture of a gastric and duodenal ulcer. In cases of retrocecal appendicitis, peristalsis does not stop, because the appendix lies outside the peritoneal cavity. Cessation of peristalsis also depends on the continued spread of peritonitis. When peritonitis becomes localized, as in cases of walled-off inflamed appendixes, peristalsis begins again, and may be hyperactive if there is partial or complete obstruction.

#### CONCLUSIONS

Auscultation of the abdomen is a valuable method of diagnosis in cases of early intestinal obstruction.

The condition and color of the bowel can often be predicted by the frequency and character of the sounds.

all night, and the patient vomited twice. I saw him the next morning.

Physical examination showed a thin, wiry man who was apparently suffering a good deal of pain. He did not look particularly ill. The temperature was 99.5°, and the pulse 88. The abdomen was not distended, and there was no rigidity. There was considerable tenderness in the right lower quadrant in the region of an old appendectomy scar—the appendix had been removed 6 years before. Peristaltic sounds were present but faint and infrequent.

Because the appendix had been removed and there was no distention or rigidity, I considered it safe to wait until afternoon before deciding what should be done. His wife was told to give him an enema.

At 4 p.m., his condition was much worse, although the pain was not quite so severe. The face was flushed, the respirations were increased, the temperature was 101°F., and the pulse was 100. Peristalsis was entirely absent. The abdomen was distended, and there was extreme tenderness in the right lower quadrant. The patient was taken to the hospital, where an immediate operation was performed.

On opening of the abdomen, there was an outpouring of dark-colored fluid. An area of the ileum, 25 cm. in length, just proximal to the cecum was black. There was a thick band of adhesions originating at the stump of the appendix and attached at its other end to the mesentery of the lower end of the ileum. The devitalized loop of intestine was resected, and an anastomosis was done. The patient died the following day.

*Comment.* This patient was seen 5 years ago, when the value of auscultation of the abdomen was not appreciated in cases of intestinal obstruction. The delay of 8 hours in sending the patient to the hospital was due to the fact that he did not present the cardinal signs of intestinal obstruction. Experience now shows that when the typical signs of obstruction, such as distention, fecal vomiting and a rise in temperature and pulse rate, become evident, it is often too late to save the patient. In this case, it should have been appreciated that the character of the peristalsis indicated advanced obstruction with beginning peritonitis. The sounds were faint and infrequent, a finding that is characteristic of the last stage of viability of the intestine. If the patient had been operated on at that time, he might have survived. Eight hours later the condition was hopeless.

**CASE 3.** A 43-year-old woman complained of abdominal pain. She had been in good health until 2 years previously, when she was operated on for an ovarian cyst. Following this operation, her health had been good until 2 months before I saw her, when she began to complain of vague abdominal pain. One month later, the pain became localized in the left lower quadrant. Three weeks later, the pain increased in severity, and the patient noticed a mass in the left lower quadrant. Three days before I saw her, the mass increased in size, together with an increase in pain and tenderness. On the previous day, the patient had vomited and had been unable to retain anything on her stomach.

Examination showed a long linear scar, 9 cm. in length, extending downward from the navel. The abdomen was greatly distended. A mass, the size of a grapefruit, was palpated in the left lower quadrant. It was extremely tender. Active peristalsis was audible over this mass and sounded close to the ear. The diagnosis of intestinal obstruction was made, and the patient was removed to the hospital.

At operation, many closely matted loops of intestine were found just beneath the abdominal wall and outside the

peritoneum. A rent in the peritoneum, about 8.0 cm. in length and corresponding to the old scar through which the intestines had emerged, was found. The intestines were not badly discolored, and seemed viable. The adhesions were separated, and the tear in the peritoneum was sutured. The patient died on the 3rd day after operation.

*Comment.* In this case, death was probably due to the length of the operation (2 hours), which was occasioned by the attempt to break up innumerable adhesions. At the time of examination, there was some question concerning the nature of the mass, but following auscultation, a definite diagnosis of intestinal obstruction was made.

**CASE 4.** A 37-year-old farmer was seen at the office. He complained of cramplike pains in the abdomen of 2 weeks' duration. For 3 days previously, they had been increasing in severity. His appetite had been poor; he had lost weight and strength.

On physical examination, the abdomen was soft; there was no distention or rigidity; no masses were felt; there was slight tenderness in the left lower quadrant, where most of the pain was located. Peristalsis was active and loud. Rectal examination was negative. The white-cell count was 11,000, with 65 per cent polymorphonuclears.

There did not seem to be any acute condition at the time. The patient was given phenobarbital to quiet down the peristalsis and told to go home and take an enema that evening and the following morning.

The next morning, his wife called up to say that he had had a very uncomfortable night, with a great deal of pain. The enemas had been unsuccessful. He had not vomited, and the temperature was normal. Physical examination was essentially the same as the night before, except that there was complete absence of peristalsis. At intervals over a period of an hour, no sounds were audible. There was no distention, no rigidity and no more tenderness than there had been the previous afternoon.

Because of complete loss of peristaltic sounds, the patient was sent to the hospital with a tentative diagnosis of intestinal obstruction. A surgical consultant saw him soon after arrival and noted no indications of an acute abdomen. The diagnosis was intestinal gripe, and the administration of salts was advised. The patient felt quite well during the afternoon, but had a very bad night. A quarter of a grain of morphine was necessary to stop the pain. The following morning, I saw the patient again, with the surgeon and two other physicians. They agreed that he did not have an acute abdomen and advised keeping him under observation. The blood count, temperature and pulse rate were normal. The tongue was coated. The abdomen was soft; there was no rigidity and only a slight degree of tenderness in the midline below the navel. However, at this time there was slight distention in the suprapubic region. The peristaltic sounds were completely absent.

During the afternoon, the patient complained of a great deal of pain. Toward evening, distention of the abdomen became marked. The temperature was 100°F., and the pulse 105. The peristaltic sounds were completely absent. The face became flushed and drawn. The consulting surgeon was again called and was convinced that there must be some trouble in the abdomen.

At operation, a mass was palpated in the descending colon about the size of a small orange, and proximal to the mass, about 46 cm. of intestine was distended and black. The patient's condition was so poor that nothing more than an enterostomy was attempted; he died the following afternoon.

relieved. During this episode, he had a temperature of 102.5°F., and there was vomiting but only slight nausea.

The patient was admitted to a Boston hospital, where he was seen by a distinguished internist on December 24. The admission temperature was 101.5°F., after which there was, for 4 days, a gradual fall to normal. There was also slight leukocytosis (white-cell count, 11,800), with 77 per cent polymorphonuclear neutrophils. Subsequent white-cell counts were 8750 and 6650. The red-cell count was 4,360,000, with a hemoglobin of 80 per cent (Sahli). The carbon dioxide combining power of the plasma was 47 vol. per cent, on the 7th hospital day. Roentgenograms of the pelvis and left hip were interpreted as showing no bony

school, and this had healed promptly and without complications. He had suffered no other injuries of note, although in playing football he had undergone considerable roughing. He had had hay fever every August since the age of 12. The family history revealed that his mother had had a tuberculous fallopian tube removed, and that a paternal uncle had died, at the age of 30, from embryoma of the testis.

Physical examination showed a very well-developed and well-nourished young man. The only abnormal findings were those about the left hip: generalized protective muscle spasm, demonstrated by attempted rotatory movements of the thigh and by the straight-leg-raising test.

FIGURE 1. Roentgenogram of Pelvis (February 8, 1939), Showing a Rarefied Area in the Left Ilium adjacent to the Acetabulum.

abnormalities. It was the consultant's opinion that some infectious process was subsiding, and the discharge diagnosis was "iliopsoas spasm, cause unknown."

After 10 days' convalescence at his home, the patient attempted to return to school, against his physician's advice. Shortly, he suffered another attack of pain, not so severe as the preceding seizure but requiring morphine on 2 successive nights. After a week of comfort, there was recurrent pain, and then a short free interval before a 3rd paroxysm. During this attack, on February 7, 1939, the patient was admitted to the Joseph H. Pratt Diagnostic Hospital. He stated that on the night before admission he had suffered the most intense recent pain, and had received several ¼-gr. doses of morphine by mouth, but, even though he was still in considerable distress, he believed that the current attack was subsiding.

It was learned that the patient had been a rather delicate child but was afterward healthy and vigorous. His tonsils and adenoids had been removed when he was 6 years old. At the age of 9, he had had lobar pneumonia, and during the illness an appendectomy had been performed. He had broken his left thumb in a scuffle at

There was no evident tumefaction or inflammation externally, but by rectal examination there were fullness and point-tenderness in the left pelvic wall. The patient complained of pain in the left groin during this examination. Another point of tenderness was found deep in the left buttock centrally.

The temperature was 101°F.

The blood showed a red-cell count of 4,750,000 with a hemoglobin of 74 per cent (Sahli), and a white-cell count of 9300 with 69 per cent polymorphonuclear cells and 2 per cent band forms. The sedimentation rate was somewhat elevated: 24 mm. in one hour, by the Westergren method. The urine contained no albumin or Bence-Jones protein. The blood phosphatase was 1.0 Bodansky unit. A roentgenogram of the pelvis (Fig. 1) showed an oval-shaped area of bone rarefaction in the left ilium adjacent to the acetabulum. The cortex in this region was thinned, and there was a faint outline of a soft-tissue mass projecting into the pelvis at a point beside the rarefied bone. In a review of the previous roentgenograms (taken in December, 1938), a slight but definite rarefaction could be seen. The findings were considered highly suspicious of

primary malignant bone tumor; the diagnoses of Ewing's sarcoma and lymphoblastoma were considered. However, on the assumption that osteomyelitis was the likely morbid process, an orthopedic surgeon decided on osteotomy.

At operation on February 9, the left ilium was entered posteriorly, and not pus but a dark, reddish, fleshy tissue was found. This had already invaded the gluteal musculature. Frozen sections proved the diagnosis of sarcoma. The pathologist's report was, "atypical Ewing's sarcoma, with well-formed reticulum." Tumor cells were seen within the lumina of blood vessels. The tissue also showed changes of recurrent inflammation.

Following the operation, there was extreme pain for 2 days, only fairly well controlled by maximum doses of dilaudid. On February 14, the patient was transferred to the Collis P. Huntington Memorial Hospital, where irradiation therapy from the million-volt machine was started. This was directed over the left pelvis, from all sides (15 x 15 cm. field), 200 r daily for 4 days, then 300 r daily for 14 days. There was relief from pain after the third day of treatment, and there was only slight roentgen sickness in spite of the large amount of radiation. Toward the end of February, the patient suffered an attack of what seemed to be grippe, with fever, cough and sore throat. When he was discharged on March 3, he had received a total of 3600 r. By March 25 (during ambulatory treatment) he had received 1500 r in addition, a grand total of 5100 r.

In March and April, the patient seemed to be making a progressive recovery. He was eating heartily and gaining weight. He was able to return to medical school but used crutches to avoid trauma to the left hip. He even played ball by hopping on the unaffected leg. At a follow-up visit on March 21, his physician found, on rectal examination, no remaining tenderness over the rami of the left pelvic bones but some soft-part thickening just posteriorly. The red-cell count was 4,010,000 with a hemoglobin of 68 per cent (Sahli), or 9.5 gm. per 100 cc. During these months, the blood sedimentation rate (Westergren) was normal, 4 and 8 mm. in one hour. The blood phosphatase was 1.25 Bodansky units.

On April 29, after 2 months of complete freedom from pain, the patient noticed a dull ache in the left shoulder; this had begun simply as an uneasiness noted during a medical-school examination. It became more pronounced during the evening, and through the next day, the pain increased steadily and kept him awake in the night. It was centered at the head of the humerus and was of a deep, boring type, with constant aching. By the 2nd day, the pain was severe and throbbing. The patient recognized that its character was identical with that of the paroxysmal pain he had suffered in his hip. There was no interference with motion of the left arm, and use of it did not increase the pain, but there was slight pain on complete inward rotation of the arm. The patient was admitted to the Outpatient Department of the Huntington Hospital, where a roentgenogram was interpreted as showing a small area of calcification in the proximal end of the left humerus. Daily irradiation was administered from May 1 through May 9, again with the high-voltage machine, a total of 1700 r to the left shoulder being given. The pain seemed to be increased in the evening after the first treatment, and on the 2nd day of irradiation there was severe nausea, but before the third treatment the pain was much lessened. By the 4th day, the patient was so much improved that he was able to make a trip to New York City for an interview about his proposed internship there.

On May 9, the patient was readmitted to the Pratt Hospital. Although he had had only slight residual

had noticed, a day or so before entrance, discomfort in the right upper chest anteriorly, associated with other pain of rather vague but moderately severe character, gradually centering about the 3rd dorsal vertebra. The chest pain had awakened him in the night before entrance, and at that time seemed to be aggravated by deep respiration. On admission to the hospital, the relation to respiration was not so evident, and the discomfort seemed to be decreasing. Physical examination showed the patient to be in apparent good health, and an increase in weight since the February admission was apparent. There were no abnormal signs in the chest, and a roentgenogram of the thorax was entirely normal. The left shoulder showed some erythema of the skin following the recent course of irradiation, but was otherwise apparently normal. The operative scar across the left buttock was well healed; there was no induration or tenderness. There was slight pigmentation about the left hip from the irradiation in February, and a lack of hair in this area. The muscles of the left thigh and leg were flabby, and there was some wasting as compared with the firm muscles of the right leg. There was an increased patellar-tendon reflex in the left leg, and slight, transitory ankle clonus. The thigh could be rotated without discomfort. The hip joints seemed equal in motion. There was no Lasègue's sign on either side. The hemoglobin determination was 78 per cent (Sahli), and the white-cell count was 5300. The sedimentation rate was normal (10 mm. in 1 hour, 21 mm. in 2 hours) by the Westergren method. Roentgenograms of the whole skeleton were made at this time. The lesion in the left ilium appeared to be somewhat filled in by reparative bone. There was nothing in the remaining parts of the skeleton to suggest metastasis. Repeat films of the left humerus showed normal bone detail in the region of the greater tuberosity. The highest temperature was 98.8°F. It was decided that the clinical evidence for a new lesion in the upper left humerus was convincing, but that the vague and nonprogressive symptoms related to the upper back and right chest were of less significance and were possibly caused by "overawareness" on the part of the patient.

During May, there were hints of continuing disease. The left shoulder was still affected, and was painful when jarred in games of catch. The patient was less vigorous and less enthusiastic. He had vaguely defined pains in the neck, back and chest. In filing papers, he had to stop frequently because of backache. There was once an alarming, sudden grating sensation on flexing the back, and a physician was consulted, but no abnormality was demonstrated. Appetite was poor, and insomnia became frequent. However, it was pointed out to the patient that he had repeatedly normal temperature readings, and a normal sedimentation rate and leukocyte count; it was explained to him how easily undue apprehension, and frustration of his strong desire to go ahead with his internship in spite of the dire outlook, might cause his pains and ill-health, through the mechanism of psychoneurosis. Thus, a regrettable delay in treatment ensued.

On May 28, the patient was readmitted to the Pratt Hospital, looking haggard and complaining of discomfort in the upper dorsal spine, associated with interscapular aching and muscular tenderness; point tenderness was found over the 3rd dorsal vertebra. Vague occipital headache was present. There was also discomfort at the lumbosacral junction. Another point of tenderness was discovered on the right 11th rib, in the midaxillary line: no friction rub could be detected, but there was slight soreness associated with deep respiration. Roentgenograms

showed right pleural metastases, although the spine appeared to be normal. The patient had a temperature of  $100.2^{\circ}\text{F}$ , a white-cell count of 8750, a relative polymorphonuclear leukocytosis (91 per cent) and some shift to the left, and an increase of the sedimentation rate by daily, serial tests. The serum phosphatase (alkaline) was still low—0.85 Bodinsky unit. Focal roentgen ray therapy was reinstituted. The patient was taken daily by ambulance to the Huntington Hospital for treatment by the million volt machine.

The episode that made rehospitalization necessary was the first of a series of six, which took place at fortnightly intervals throughout the summer (Fig 2). Every episode was announced by new pains, as well as by malaise and rigors, and was confirmed by a striking rise in the sedimentation rate and by fever (of slight to moderate de-

pernicious type preventing proper fluid and caloric intake). Nausea was not alleviated by intravenous glucose and saline solutions, nasal oxygen or peroral and parenteral thiamin chloride.

The patient was taken back to the Pratt Hospital in mid June, at a time of striking improvement. For a few days, his progress was encouraging. Roentgenograms indicated complete disappearance of the pleural lesions; it seemed that the therapeutic weapon was competent. Yet pleural discomfort was still present, and when the patient coughed he was conscious of tender points along the spine.

The next flare up was predicted by throbbing headache which developed during the last week of June and reached its acme by the 2nd day of July. It was left-sided over the eye. A roentgenogram of the skull (Fig 3) showed

FIGURE 2 Chronological Chart of Sedimentation Rates, Pain, Temperatures, White Cell Counts and Radiation Therapy

gree) and rise in the leukocyte count. Irradiation was increased at every exacerbation, and the bombardment was followed, more or less promptly, by relief from pain and by subsidence of the fit of illness. As the vital signs reapproached normal ranges, and the sedimentation rate lessened steadily, there occurred regularly a period of comfort and a betraying appearance of marked improvement. This was always short lived, however, new pains soon arrived to announce the next cycle.

The first period of relief, in the early days of June, gave way to a paroxysm of distress about the spine—a glass brick, due to alarming muscular spasticity, was evident. There was a return of pleuritic pain and later a friction rub, this time at the left costal border, along with a point of tenderness. Marked prostration signified the severity of the attack; morphine was required for the mounting pain. The patient was transferred to the Huntington Hospital for intensive irradiation. In spite of this treatment, he had much pain for several days—as well as exhausting nausea and vomiting, which were attributed to the heroic therapy. Roentgen sickness was from then on an enervating complication. The vomiting was of a

scattered lesions in the calvarium. There was slight epistaxis. It was necessary to direct irradiation to the head and this entailed interruption of the program of systematic coverage then in progress. After the second retreatment to the head the patient was decidedly more comfortable. The headache returned after another day, in spite of continued irradiation. As in previous attacks, other areas were excited, and throbbing pain developed along the right pelvic brim (Local hyperesthesia alone had been noted 2 weeks earlier, at an analogous time in the preceding episode). There was also intense pain in the lower left thigh. At length improvement was attained and in early July there was a series of days without pain and with only the relentless x-ray nausea.

The fourth episode in the generalization of the disease occurred in mid July, and was marked by pain in the left arm and, shortly thereafter, by severe pain in the right shoulder and arm and in both thighs. Neither at this time nor, in fact, during any episode did pain occur in the extremities distal to the elbows and knees. At this exacerbation the patient experienced symptoms rumored in association with the original lesion: point tender

ness in the left buttock and paresthesia in the left groin and about the hip. It had to be admitted that roentgen-ray therapy was being used for its palliative effect alone, and that more of the noxious irradiation than the weakened condition warranted would be needed for the widespread lesions.

There was about a week of some comfort (toward the end of July) before the fifth episode began. Pain was localized once more in the left hip and groin, in the right shoulder and neck, associated with marked lameness of the musculature, and in the right chest, with respirations; point tenderness in the 5th rib, anterolaterally, could be elicited. A short time later, pain was also

FIGURE 3. Roentgenogram of Skull (June 24, 1939), Showing Scattered Metastatic Lesions in the Calvarium.

localized along the left costal border anteriorly (aggravated by hiccup), in the occiput and across the back at the level of the 12th dorsal vertebra.

On August 1, the patient was transferred to the Huntington Hospital because it was not decided to begin treatment with a purified Coley's toxin (concentrated filtrate of *Bacillus prodigiosus*). He had become unnaturally lean. At the time of transfer, the fifth episode was near its height, the pain being most marked in the left iliac crest and in the right chest. On August 2, the first dose of filtrate, given intramuscularly, was followed in 3 hours by a severe chill, a sharp fever of 103°F. and convulsive vomiting. After 2 weeks, additional and successively stronger doses were given every 4 or 5 days—six injections in all. Intravenous barbiturates alleviated the vomiting.

A brief respite on August 10 marked a point analogous with the time of relief experienced during subsidence of previous episodes. But prompt return of back pain (dorso-lumbar and cervical) indicated the proximity of the ensuing spell. There were warnings also in occipital and left frontal headaches, which increased and became throbbing in character during mid-August, and in anesthetics of the left lower lip, adjoining skin and adjacent buccal mucosa. In addition, on August 16, diplopia appeared; there was a left external rectus palsy. During these days, pain was again present in the left iliac crest, in the lower

right chest laterally and in the lumbar region. A striking spasticity of the left upper rectus muscle of the abdomen, which had been noted in conjunction with the left costal-border distress early in the month, reappeared. Very severe back pain was precipitated by an injection of filtrate on August 19. A continuation of the mid-August seizure was exhibited by distressing pleuritic pain, with palpable friction-rubs, first in the left side and then in both. The throbbing left-sided headache was recurrent; there was a discharge of bloody, tenacious mucus from the left nostril. Associated with left iliac pain, the adjacent femoral musculature showed continual and painful spasm, with later local pitting edema and a peculiar doughy consistence.

Roentgenograms in mid-August demonstrated apparently clear lung fields. There was erosion of the left iliac crest; the hip joints were normal; the site of the original tumor appeared to be somewhat more filled in by reparative bone. In the skull, no abnormal changes could be detected in the sella turcica, petrous ridges and paranasal sinuses; the rarefied foci throughout the cranium were not so sharply defined as formerly.

Toward the end of August, and at a time of progressively slowing erythrocyte sedimentation, the patient became more vigorous and had several comparatively comfortable days. Morphine was required, nevertheless, at regular intervals, and even in large doses did not completely relieve distress. There was excruciating pleuritic pain, and all the other familiar pains were revived, following a fifth injection of filtrate on August 28.

Terminally, there was respiratory embarrassment. Brief periods of hyperpnea and polypnea began to appear about a week before death. On September 3, the patient had noted marked air-hunger in the early morning, and this became his main concern in the forenoon. A transfusion did not lessen the dyspnea. The breathing was of the Kussmaul type, with terminal expiratory effort. A severe acidosis was indicated by a plasma carbon dioxide combining power of 13 vol. per cent. Examination of the chest indicated accumulating pleural fluid, especially on the right side. A marked bleeding tendency was apparent at every hypodermic injection; the bleeding time was prolonged to 9 minutes; platelets appeared to be much reduced. By the use of intravenous sodium bicarbonate, the plasma alkalinity was increased to a normal level. Yet the patient recognized the fact that the dyspnea was not commensurately improved. He died on September 5, a year after the onset of symptoms.

*Autopsy.* Except for advanced infiltration of the lungs, there was a striking absence of tumor in the viscera, and the skeleton was shown to be the chief depository. The brain, liver, spleen, kidneys, heart and intestine were essentially normal. A large amount of tumor was found in the pelvis adjacent to the original lesion; it had infiltrated the adjoining musculature. The bulk of this tumor was necrotic, and there were many hemorrhages centrally in the larger nodules. The tissue was grayish and softened, with the appearance of brain tissue.

There were lesions arising from the ribs that projected into the parietal pleura on both sides, and the surface of the left diaphragm was covered with tumor nodules. The vertebrae showed diffuse sarcomatous infiltration, especially advanced in the 12th dorsal vertebra. In the base of the skull, the left petrous bone and the sphenoid and left ethmoid sinuses contained tumor; the calvarium, on transillumination, showed spotty infiltration. No tumor could be found in the upper left humerus (the site of the earliest secondary deposit). The mediastinal and pelvic lymph nodes contained tumor. There was bloody pleural

fluid in both sides. The bony lesions were destructive, new bone was not present.

Microscopically, the lesions were typical of those of Ewing's sarcoma (Fig. 4).

**Radiotherapeutic note.** According to the roentgenologist (Dr. Richard Dresser), from the radiotherapeutic standpoint, several interesting observations were made in this case. Roentgen rays approaching in average wave length the gamma rays of radium were employed. Although huge amounts of radiation were given, the skin showed remarkably little reaction, and at no time was it necessary to halt therapy because of damage to the superficial structures. Although the patient was by no means free from roentgen sickness, the general untoward reaction to the superhard radiation was less than would have been antici-

FIGURE 4 Photograph of a Section of the Tumor.

pated from corresponding doses of 200 kilovolt roentgen rays. The clinical response to radiation was essentially the same as that observed in a number of other such cases that is, a brief respite from symptoms with general improvement, only to be followed by metastatic manifestations and a progressively downhill course. Although at autopsy much tumor tissue was found at the site of the primary lesion, it is difficult to say how much of this was the original growth and how much metastatic disease. It is well known that the secondary deposits of any growth are prone to be less radiosensitive than the original neoplasm.

#### COMMENT

**Mortality statistics.** Ewing,<sup>5</sup> in 1921, singled out this neoplasm of bone as an entity because of its response to radiotherapy (radium). Its incidence is given as between 10 and 15 per cent of malignant tumors of bone.<sup>6</sup> Its pre-eminent malignancy<sup>3</sup> is attested by the published reviews of series of cases. In 1926, Connor<sup>2</sup> found 11 per cent "cures" in 54 cases (52 from the Registry of Bone Sarcoma and 2 from the Massachusetts General Hospital). In 1930, Copeland and Geschickter<sup>7</sup> reported that 86 of 99 patients had died, but that 13 were apparently well: 3 for four and a half to five and a half years, and 8 for three to five years. In 1939, Geschickter and Maseritz<sup>8</sup> gave a figure

of 94 per cent fatalities in a group of 135 cases. Meyerding<sup>1</sup> has been able to demonstrate a patient who was well five years after biopsy and irradiation, and another who showed no recurrence fifteen years after curettage, irradiation, Coley's toxin and, finally, amputation. In 1938, Meyerding<sup>9</sup> also added to the literature a ten-year cure effected by means of Coley's toxin in addition to irradiation therapy, and an eleven-and-a-half-year cure by amputation followed by irradiation. Desjardins, Meyerding and Luddy<sup>10</sup> observed 6 patients of a series of 24 so treated who were alive two to twelve years after treatment by irradiation alone. On the other hand, W. B. Coley<sup>11</sup> stated, in 1935, that no five-year cures of Ewing's tumor of the long bones were effected by irradiation alone, in either his series of 50 patients or in the group of 100 cases in the Registry. He<sup>12</sup> had pointed out earlier that half the five-year cures in the Registry had had his toxin as part of the therapy. It is arresting to read that advanced and inoperable cases have thus been reclaimed: 12 of 22 inoperable patients (6 treated by toxins only, and 6 by toxins in addition to x-ray) have been well for five to seventeen years. In 1931, W. B. Coley<sup>13</sup> presented 6 cases apparently cured by toxin and radium therapy after extensive metastases. The case presented by Christian and Palmer<sup>14</sup> is an example of amazing therapeutic triumph, but the course was leisurely and not fulminating like that of the more fatal tumors. Simmons<sup>15</sup> has pointed out that the Registry contains no case of a cure of bone sarcoma by irradiation alone. In 47 cases of bone sarcoma at the Massachusetts General Hospital from 1920 to 1932, inclusive, he found 8 cases of Ewing's sarcoma, all of which were fatal; 4 had been treated by amputation and 4 by irradiation, and these had shown the regular but only temporary response. Both he and B. L. Coley<sup>16</sup> stated recently that they have not observed a single authenticated case of a five-year cure.

**Therapeutic procedure.** Simmons<sup>17</sup> believes that there is some hope if radical amputation can be carried out. Copeland and Geschickter<sup>7</sup> consider radical surgery combined with irradiation to offer most in therapy. Geschickter and Maseritz<sup>8</sup> approve biopsy, after a preceding roentgen therapeutic test, to be followed by surgery—resection of shaft, or amputation in the weight-bearing bones of the lower extremity. B. L. Coley<sup>16</sup> urges that biopsy be done before irradiation because of the distorting effect of roentgen rays on the cells, and the ensuing difficulty in microscopical diagnosis. W. B. Coley<sup>11</sup> agrees that amputation is not to be spared as a therapeutic necessity, and

has said that irradiation should be depended on only in the inoperable case. He urges biopsy, if the diagnosis cannot be made without it. Prolonged toxin therapy is advised, to be given adjuvantly in surgical intervention. Meyerding<sup>9, 17</sup> insists that early irradiation is the method of choice.

*Prognosis.* It was observed by Ewing<sup>18</sup> that the mortality is higher in younger patients. He estimated the duration of the disease to be from one to three years. Twelve months is given as the average duration of symptoms before the patient is seen. Copeland and Geschickter<sup>7</sup> state that the average duration of symptoms preoperatively in patients who live is twenty months, whereas in the fatal cases it is only six months. Thus, it is possible to predict the course by the time of development of severe symptoms. Simmons<sup>15</sup> has stated that the prognosis in bone sarcoma depends more on the degree of differentiation of tumor cells than on any other factor. A corollary conclusion is that, once metastases appear, the outlook is grave, regardless of the type of therapy.

*Proper clinical attitude.* It is well to remember that the discouraging statistics contain a considerable element of delayed diagnosis. Desjardins et al.<sup>10</sup> state that, in a group of 42 cases of endothelioma of bone, an accurate clinical diagnosis was made in only 9 cases. Other contributory reasons for the many failures might be found in poor roentgenography and inadequate irradiation. Even if it must be admitted that few of the tumors have been permanently controlled, it does appear that there was effectual intervention in the favorable cases. The striking radiosensitivity of Ewing's tumor seems to present prima-facie evidence for an eventual control by roentgenotherapy. Yet the strong suggestions of underlying constitutional nature, as well as the inflammatory character of the growth, enliven the hope for successful use of a perfected toxin. Connor's<sup>2</sup> exhortation may well be repeated after fifteen years: the disease "should not be looked upon as hopelessly fatal from the start. . . . A consistent and persistent attack . . . will frequently control it temporarily, and . . . in a number of cases permanently."

#### CONCLUSIONS

The clinical story in Ewing's sarcoma of bone reflects the appearance and progress of a recognizable pathologic entity, and is of decided importance in diagnosis and treatment, especially in cases in which the lesion is hidden or the process is histologically and roentgenographically obscure. The salient clinical characteristics are: insidious onset, regular alternation of episodes of pain and periods of comfort, and progressive intensifica-

tion. The last is a feature of the component episode, as well as of the total course.

Early diagnosis is adjured because the tumor possesses unique radiosensitiveness, and treatment must be instituted prior to generalization of the disease.

The natural history of the tumor is of value in avoiding the common, erroneous diagnosis of osteomyelitis, which is strongly suggested by the inflammatory signs. Fever and leukocytosis during episodes may be striking.

On the other hand, technical signs of active disease may be so slightly suggestive that the physician departs from consideration of a morbid process and begins to suspect emotional difficulties.

Such an interpretation of events encourages delay in treatment. The patient's recognition of the recurrence of familiar pain should be given full credence.

The roentgenogram is not a dependable index of integrity of bone. Lesions undeniable from the clinical standpoint may remain unvisualized until an advanced stage.

Although the factor of hereditary predisposition to neoplasm is suggested by the incidence of embryoma of the testis in an uncle, there was in the case presented no indictable precipitating cause, such as specific trauma.

This case supports the idea that prognosis is chiefly dependent on the degree of malignancy. The fulminating character of the neoplasm in this patient was indicated by the rapid evolution and resolution of the disease. The growth-behavior of the tumor is the fundamental criterion in prognosis. To say that the early appearance of secondary lesions removes a patient from the group of those who may get well is simply to admit the primacy of this concept.

The effectiveness of irradiation was demonstrated in this case by prompt subsidence of symptoms and by reinstitution of apparent health for two and a half months. Since after this period, however, secondary neoplastic foci appeared, it must be concluded either that metastasis had already occurred before irradiation of the ilium or that dissemination proceeded afterward, from radioresistant cells in the parental tumor.

In spite of almost relentless irradiation in heavy dosage, evidences of insufficiency of the bone-marrow did not appear until the terminal days of cachexia. Even then, an abundant polymorphonuclear leukocytosis was possible.

The metastatic phenomenon of predilection for bone indicates a favoring milieu there, in contrast with visceral inhospitality.

In the case presented, it was striking that at the times of reactivation, and when new lesions were appearing, old sites of metastasis became painful again. Such manifestation of a general, co-ordinated development was corroborated in the cycle of variation in rate of blood sedimentation, which took place with regularity in spite of irradiation, toxin therapy and progressing anemia. Furthermore, the timing of cycles during the stage of generalization was apparently the same as that when the primary tumor was evolving. This maintenance of a basal rhythmicity throughout the whole active course points to a supervisory regulation of growth in the constellation of tumors, and reflects the interplay of neoplastic increment and systemic readjustment. One gains a larger, biologic concept of the disease if one considers the tumors, not as independent lesions, but as homologous neoplasms obeying an intermittent irresistible force.

## MEDICAL PROGRESS

### SYPHILIS

C. GUY LANE, M.D.,\* AND G. MARSHALL CRAWFORD, M.D.†

BOSTON

DURING the past year, there have been so many publications of interest about syphilis that it is again difficult to select material for a progress report. It is of primary interest that the campaign to control syphilis continues unabated and should before long produce noticeable changes in the incidence of the disease. This is especially true in the larger cities, where there is already an apparent drop in syphilis in presumably representative samples of the population.<sup>1</sup> Heretofore, smaller cities and rural communities showed the lowest incidence of syphilis. This reversal seems to indicate that the work has been either less actively pursued in the smaller cities or less effectively promoted. The campaign also has produced numerous publications regarding the effort to prevent venereal disease among the nation's

military forces.<sup>2</sup> Since many army camps are at some distance from towns and cities, the vendors of feminine diversion have taken to wheels. Evidently, prostitution has motorized more rapidly than the army. Regulations have been promulgated, and large restricted areas have been set aside in which trailers and roadside stands are not permitted around certain military posts.

### PUBLIC HEALTH

The first item of note is the recent passage in Massachusetts of a premarital-examination statute. The Massachusetts law<sup>3</sup> differs from most in that there is no provision preventing marriage, regardless of the presence of disease. It is merely required that applicants be examined, and that both parties be informed of the presence of infectious disease and the possibility of transmitting it in marriage and pregnancy. Editorial comment<sup>4</sup> on this statute has been favorable. A similar law has been operating in Virginia for several years, with apparently satisfactory results.<sup>5</sup> It is hoped

Reprints of articles in this series are not available for distribution but the articles will be published in book form. The current volume is *Medical Progress Annual*, 1940 (Springfield, Illinois: Charles C. Thomas Company, 1941) \$4.00.

\*Clinical professor of dermatology, Harvard Medical School, chief, Department of Dermatology, Massachusetts General Hospital.

†Assistant in dermatology, Harvard Medical School, assistant in dermatology, Massachusetts General Hospital.

that this measure will restrain those who should not marry and stimulate them to undergo treatment—perhaps more effectively than if marriage were made illegal. A survey of reports from twenty-six states having premarital laws<sup>6</sup> indicates an incidence of 1.3 per cent positive tests among 677,000 persons. This is lower than the rate for the population as a whole, and should have brought approximately 8800 people under observation. One difficult problem is reciprocity between states having these premarital laws. This matter has already been considered,<sup>7</sup> but the solution is probably somewhat in the future. In one state, a premarital law has apparently reduced congenital syphilis 50 per cent in four years.<sup>8</sup> Marriages were fewer at first, but have been steadily increasing. A particularly good study of the incidence of syphilis by Clarke and his associates<sup>8</sup> was extremely critical of the data previously utilized, and compiled statistics on more than four million people. Each report was reviewed according to rigid criteria, and many groups were discarded, the final analysis being based on about two million cases. The crude rate for the incidence of syphilis was 3.24 per cent on a nationwide basis. Figures for various population groups would cover wide variations. For example, the prevalence of syphilis among the first million selectees and volunteers was 4.52 per cent.<sup>1</sup> This is subject to some possible modification because follow-up studies had not been completed on all positive cases at the time this report was compiled. Statistics should be broken down to cover various sectional groups so that the greatest effort can be directed among the portions of the population that are most heavily infected.

#### SEROLOGIC TESTS

Much effort has been expended on analyzing and improving serologic tests for syphilis. There has perhaps been more confusion in the mind of the profession regarding blood tests than on any other matter relating to this disease. The fourteenth supplement to *Venereal Disease Information*<sup>9</sup> is a monograph devoted to this problem. Every phase of serologic tests for syphilis and their interpretation is thoroughly covered. A review of this work is impossible here, but the supplement can be obtained from the United States Public Health Service for a pittance.

The increasing number of tests for syphilis has led Moore and Eagle<sup>10</sup> to suggest standardization of serologic reports. The more tests one can employ on a given specimen, the greater is the possibility of an accurate result. It is the interpretation of variant reports that is confusing, and the

laboratory director should be the best qualified person to unify conflicting laboratory findings. Thus, these authors recommend that a single report of positive, negative or doubtful be returned from the laboratory, regardless of the type or number of tests employed. This composite report would simplify and clarify the utilization of laboratory data. No information of diagnostic significance would be withheld, since the results of all individual tests should be given on the back of the laboratory slip. A study of the specificity of serologic tests carried out on 40,545 college students of both sexes showed 62 cases (0.15 per cent) that were positive or doubtful,<sup>11</sup> and these data were confirmed by repeat tests. Half these cases failed to exhibit any evidence or history of syphilis. By correlation with the proved cases of syphilis, only 10 cases were considered to have possible false-positive reactions. This incidence (1:4000) of questionable false-positive results seems sufficiently small to justify, as a general public-health measure, the diagnosis of syphilis in clinically normal persons on the basis of repeated positive serologic tests, even in the absence of history or clinical evidence of syphilitic infection.

Moore and Eagle<sup>12</sup> have been investigating quantitative serologic tests for syphilis since 1928, and their report covers 1665 cases. It is essential that these tests be done in series by the same laboratory; otherwise, they are not comparable, and it is emphasized that a single quantitative test is practically useless. Therefore, such procedures are of little value as routine diagnostic measures, nor are they an expression of the severity or gravity of the infection. It has not yet been possible to determine accurately the prognostic value of serial quantitative tests for syphilis in the course of treatment.

It has been conclusively demonstrated that patients with infectious mononucleosis give a positive serologic reaction for syphilis that may persist as long as two months. Publications on this point have been quoted in previous progress reports. It is interesting to note a report of an epidemic of mononucleosis without clinical signs or symptoms.<sup>13</sup> Sixteen out of 108 convalescent rheumatic-fever patients developed mononucleosis during a six-month period. The first case was accidentally discovered during a routine leukocyte count. Blood Wassermann reactions were checked in only 5 cases and were negative in all. This report gives rise to interesting speculation: if infectious mononucleosis exists in an asymptomatic form and if such cases occasionally show positive blood tests, another obscure cause for false-positive serologic tests for syphilis exists. It is unfortunate

that only 5 cases were tested and that only the Wassermann test was employed

Another episode has apparently been proved to provide false-positive serologic reaction for syphilis. Lynch and his associates<sup>14</sup> found that 43 (16 per cent) out of 263 patients exhibited positive tests for two to four months after vaccination for small pox. The same phenomenon was encountered in a study of 20,000 serologic tests for syphilis among Navy personnel after vaccination.<sup>15</sup> Typhoid inoculations did not produce this effect on the serologic tests.

### TRANSFUSION SYPHILIS

The 1940 progress report<sup>10</sup> called attention to the successful use of arsphenaminized citrated blood in the prevention of transfusion syphilis. Further work has been carried out along this line by Eichenlaub and associates,<sup>17</sup> who suggest that 0.01 gm of Mapharsen be added to the sodium citrate solution when blood is withdrawn from the donor. This recommendation is based on a study of 41 cases of transfusion syphilis in which 16 of the donors had syphilis that was not detectable by laboratory methods or physical examinations. The amount of Mapharsen suggested was found to be capable of sterilizing 500 cc of blood known to contain *Treponema pallidum* (rabbit experiments). These authors believe that if the procedure is not accepted as routine, it should at least be used when there is not time to investigate the donor or when any doubt of the absence of syphilis exists. The increase in utilization of blood banks has given rise to another phase of transfusion syphilis. Studies by Turner and Discher<sup>18</sup> and by Bloch<sup>10</sup> are encouraging. Experimental results with citrated blood to which a suspension of virulent *T. pallidum* was added indicate that the infectivity of the treponemes in citrated blood rarely persists for longer than three days at refrigerator temperature. Therefore, there is apparently a definite risk if blood has been preserved for less than seventy-two hours, but not thereafter unless the donor had early syphilis. It is probable that any blood stored for four days or longer can not transmit syphilis.

### CLINICAL PROBLEMS

**Extragenital chancre.** Wilk and Holman<sup>20</sup> reviewed 841 cases of primary syphilis observed over a period of twenty-five years, among which were 68 cases (8.0 per cent) of extragenital chancre. In 39 cases (57.3 per cent), these occurred on the lip. In decreasing order of incidence were lesions on the tonsil, tongue, pharynx, female breast, forehead, chest and anus. Noteworthy cases and the circum-

stances surrounding them were described in detail. The failure of early diagnosis, particularly in unusual locations, was emphasized. Syphilis should always be considered in the face of any persistent lesion with regional lymphadenopathy that does not respond to ordinary therapy.

**Secondary syphilis.** Thomas and Goldstein<sup>21</sup> reported 23 cases of chronic syphilitic tonsillitis, 20 being misdiagnosed before coming to their clinic. The duration varied from two weeks to over three months, and all but one patient showed a secondary eruption. There is nothing characteristic about the appearance of these throats, but they must be differentiated from Vincent's infection and diphtheria. Routine serologic tests for syphilis and a careful examination for other signs established the diagnosis.

**Transmissibility of syphilis.** Pariser<sup>22</sup> studied the infectiousness of vaginal secretions and menstrual blood of 30 untreated syphilitic women by injecting these secretions into rabbits. Vaginal infectiousness was periodically recurrent rather than continuously present, and depended on the presence or absence of lesions. No estimate could be made of the frequency of cervical relapse or of its end point. One infectious relapse occurred six and a half years after the onset of the disease. Physiologic secretions were not infectious in the absence of open lesions.

**Bone and joint syphilis.** Buchman and Lieberman<sup>23</sup> reviewed 89,000 orthopedic cases observed over a period of ten years. Of these patients, 119 (0.13 per cent) had lesions of the bones or joints due to syphilis, 25 were congenital cases, of which 3 exhibited a negative blood reaction, 27 of 84 patients with acquired syphilis showed a negative reaction. The authors attributed this low incidence of bone and joint syphilis to the relative infrequency of lesions of orthopedic importance in the presence of syphilis.

**Cardiovascular syphilis.** Gelperin<sup>24</sup> reported an interesting analysis of 7638 autopsies in which 700 cases (9.1 per cent) with microscopic evidence of syphilitic aortitis were found, excluding developmental complications; he suggests that patients with late latent syphilis, without adequate treatment, be considered as having active syphilitic aortitis. Doubtless, there are dissenters to this opinion. Berk,<sup>25</sup> reporting a clinical and electrocardiographic study of cardiovascular syphilis, believes that the only safe method of diagnosing early syphilitic aortitis with coronary ostial stenosis is with a positive electrocardiogram after a positive exercise test. After the age of fifty, however, he regards this finding as more probably due to coronary sclerosis on a nonsyphilitic basis.

Stewart and Smith<sup>26</sup> found that the administration of potassium iodide causes changes in the electrocardiogram and cardiac rhythm that may be falsely attributed to coronary occlusion. These "toxic manifestations" disappeared after the drug was discontinued.

*Congenital syphilis.* Ingraham et al.<sup>27</sup> have published a comprehensive report on infantile congenital syphilis. It covers a five-year follow-up on 230 children of syphilitic mothers. Re-examination of 70 per cent of the survivors four or five years later revealed no congenital syphilis that had been missed by x-ray and serologic studies during infancy. The mortality among syphilitic infants was 33 per cent, as compared with 10 per cent in the nonsyphilitic group; over three times as many died without therapy as with it, even when inadequately treated. Ingraham believes that hyperpyrexia from intercurrent disease may enhance good results. He also reviews the recent advances in the serologic and roentgenologic diagnosis of infantile congenital syphilis and emphasizes close co-ordination in interpreting blood and roentgenographic changes. Considerable attention is given to titrated serologic studies, and their great value in the early weeks of life is emphasized. Occasionally, a significant change in the titer may not occur until four to eight weeks after the child is born. Sarnat and his collaborators<sup>28</sup> described changes found in the unerupted permanent teeth by roentgenographic study of patients with congenital syphilis; disturbances in development occurred in the neonatal period and earliest infancy. These may be diagnostic when x-ray films of the long bones show nothing, since the teeth changes are permanent, whereas bone lesions are subject to resorption. This is a useful contribution, and one can readily agree with the postulation of the authors that x-ray examination of unerupted teeth should be carried out in conjunction with studies of the long bones. Koons and Kissane<sup>29</sup> studied 100 children with congenital syphilis and 335 others with cardiac disease. No syphilitic heart disease was found, and the authors concluded that syphilis can be practically disregarded as a cause of cardiac disease in children. This bears out a long-accepted corollary. The role of ariboflavinosis in interstitial keratitis has not been entirely clarified. Johnson and Eckardt<sup>30</sup> were unable to produce keratitis in syphilitic rabbits by placing them on a diet deficient in riboflavin. These authors believe that the corneal changes seen with the slit lamp in riboflavin deficiency are not typical of syphilitic keratitis.

*Syphilis and pregnancy.* Peckham<sup>31</sup> studied the effect of syphilis and its treatment on toxemia

of pregnancy in 13,742 consecutive deliveries and found the incidence of toxemia somewhat lower in syphilitic than in nonsyphilitic patients. There was no correlation between the stages of syphilis and frequency of toxemia. The lowest incidence of toxemia was in syphilitic patients treated before, but not during, gestation, the amount of treatment employed being without significance. Half the patients receiving therapy during pregnancy had evidenced toxemia before antisyphilitic treatment was begun. It is obvious from this study that the various degrees of toxemia of pregnancy are entirely unrelated to both syphilis and its therapy.

*Neurosyphilis.* Bottema<sup>32</sup> had the unique opportunity of observing 1470 cases of syphilis in the Dutch Navy that were followed for thirty years. Careful records and very thorough checks on clinical and laboratory findings were available for the entire time. The patients were divided into four groups, as follows: untreated; those receiving mercury therapy only; those given small amounts of arsphenamine; and those receiving intensive arsphenamine therapy. A striking progressive decrease of morbidity in each group left no doubt regarding the value of even small amounts of therapy. This is interesting in view of the theory, maintained by some, that small amounts of the arsphenamines are conducive to the occurrence of neurosyphilis. Alpers and Lesko<sup>33</sup> call attention to the incidence of neurosyphilis with negative cerebrospinal-fluid examinations. Varying percentages of negative fluids are reported for the different types of neurosyphilis, the highest being 23 per cent in vascular neurosyphilis. In many cases of neurosyphilis of all types in which the laboratory reports are negative, clinical symptoms not only remain, but continue to progress. This is especially true of tabes dorsalis and vascular neurosyphilis. Alpers and Lesko conclude that these cases illustrate the tendency to emphasize too strongly the laboratory data to the exclusion of the clinical facts.

*Syphilis and diabetes mellitus.* McDaniel, Marks and Joslin<sup>34</sup> reviewed 15,095 patients with diabetes and found 258 cases (1.7 per cent) of syphilis, 87 per cent of which were latent. In their study, these authors failed to find any "syphilitic diabetes." Not a single case of cure of diabetes was brought about by optimum antisyphilitic therapy. Williams<sup>35</sup> observed that 23 of 1000 patients with severe diabetes and low carbohydrate-tolerance tests, for whom large doses of insulin were required and whose metabolism was difficult to adjust, frequently showed "subpositive" serologic tests for syphilis. Treatment was found to serve

no useful purpose and was often upsetting. He concluded that there was no causal relation between syphilis and diabetes.

*Syphilis and tuberculosis.* The management of syphilis in the tuberculous patient has been discussed by Murphy and Bromberg.<sup>36</sup> Approximately 9 per cent of an adult tuberculous group was found to be syphilitic, which is somewhat higher than the usual figure for this type of patient. These authors confirm the existing belief that syphilis does not materially alter the prognosis of tuberculosis, or vice versa. It was indicated that tuberculous toxemia may occasionally contribute to temporary false positive serologic reactions for syphilis. In hopelessly advanced tuberculosis, any other treatment would be superfluous. Cardiovascular and cerebrospinal syphilis may be debilitating and even fatal in a patient with advanced tuberculosis who otherwise might maintain a satisfactory equilibrium. It is interesting to note a paper by Fujimori<sup>37</sup> concerning the influence of syphilis on the resisting power of a living organism. It was found that experimental syphilitic infection decreased resistance and rendered the animals more susceptible to other infections.

#### THErapy

*Early syphilis.* An outstanding study on the treatment of syphilis has been that of Padget.<sup>38</sup> A very difficult problem in evaluating treatment, especially new drugs and new methods, has been the lack of necessary long-term statistics to show the end results. In a disease that is so chronic, insidious and prone to relapse, the first results of treatment are of value only for prognosis of the immediate future. It is a long-term follow-up of therapeutic results in early syphilis by modern methods that Padget has been able to present for the first time. Five hundred and fifty-one patients were completely re-examined five or more years after the termination of treatment "Cure," as defined by Padget, consisted either in reinfection or in freedom from symptoms, negative physical examination, repeatedly negative serologic reactions for syphilis, normal cerebrospinal fluid and normal roentgenograms of the cardiovascular stripe. In the light of these criteria, only slightly less than two thirds of these cases achieved cure, the mean period of observation being about eleven years. Two hundred and sixty-eight patients were examined after five years had elapsed and, again, at the end of ten years. No case showed a less satisfactory result at the end of ten years than after only five years. This is perhaps one of the most significant features of the study and indicates that, in a patient with early syphilis ade-

quately treated by modern methods who maintains such a "cure" for five years, the possibility of further trouble is extremely remote. Padget's other findings in the study of this group are confirmative of the accepted opinions regarding race, sex, stage of disease at onset of treatment and so forth. The final results were found to be dependent on both the type and the amount of treatment, the alternating continuous system of therapy being clearly superior to other programs. It was emphasized that the continuity must be absolute, especially in the first six to twelve months; 90.4 per cent of patients who had unbroken treatment for the first year were cured, which was the highest figure. The worst results were obtained in the seropositive primary cases, in only 55 per cent of which cure was achieved, neurosyphilis being more than twice as common in this group as any other. Padget's paper is of considerable value in that it has at last provided the absolute proof of several cardinal principles in the treatment of syphilis as emphasized by the modern school of syphilologists. In the light of this, a review by Cole<sup>39</sup> is very timely: it gives an excellent survey of the problems of the general practitioner in the treatment of syphilis and provides cogent answers.

*Bismuth compounds.* It is only in approximately the last twenty years that bismuth has been used in the treatment of syphilis. Walsh and Becker,<sup>40</sup> who have reviewed the status of this drug, emphasize the fact that it cannot be relied on as the sole antisyphilitic drug to the exclusion of the arsphenamines. According to these authors, the present consensus seems to be that bismuth salicylate in oil is the most suitable from the standpoint of therapeutic effect, low toxicity and prolonged action. A plan of treatment that includes the advocacy of a much larger number of bismuth injections than is usually employed, especially in neurosyphilis, is outlined, but their report indicates slightly better results. Considerable experimental work with oral bismuth administration in animals suggests its effectiveness in early syphilis. A recent paper by Hanzlik and Van Winkle<sup>41</sup> is confirmatory. Lambert,<sup>42</sup> however, shows that oral bismuth is not suitable for the treatment of early syphilis in the human organism. Six seronegative cases of primary syphilis and 2 in the secondary stage were treated with Sobisminol, six to nine capsules daily, for a period of nearly four months each. Five of the seronegative primary cases developed a positive blood Wassermann, and 4 of these 5 developed a clinical secondary stage despite the above therapy. The implication is obvious.

*Arsenical therapy.* Stokes and Beerman<sup>43</sup> reviewed the use of trivalent arsenicals in syphilis

from the standpoint of recent advances, comparisons and evaluations. It is a very comprehensive study including a discussion of nine different drugs, methods of testing, new technics, the "five-day plan," the laboratory value of drugs compared with their usefulness to the practicing physician, to the expert and to the demands of the public-health officer. This paper is certainly worth reading in the full text by those who aspire to any degree of familiarity with these drugs. It is brought out that although Mapharsen is apparently the best drug in many respects, there is as yet insufficient study of infectious relapse following its use. The value of Bismarsen in childhood and in cardiovascular syphilis is stressed. In the end, however, the authors consider arsphenamine the most effective drug in everything except central-nervous-system syphilis.

*Interstitial keratitis.* Klauder and Vandoren<sup>44</sup> presented an excellent report on 532 cases of interstitial keratitis, with particular reference to treatment. All the cases, which were pooled from five institutions, were treated or observed for at least one year. The median age at onset was twelve years in females and thirteen years in males. The two commonest stigmas present in conjunction with the keratitis were Hutchinsonian teeth (40 per cent) and bone and joint lesions (35 per cent). It was interesting that 42 per cent of the cases were bilateral within a month of onset, and that 71 per cent became bilateral within two years. The figure then crept very slowly to 79 per cent at the end of ten years. The fact that hyperpyrexia (malaria or hyperthermia) should be instituted at once was emphasized. Immediately following this, at least twenty intravenous arsenical injections were advocated, in conjunction with bismuth. This combined treatment should be started between the fever treatments if malaria therapy is not used, and the first few injections of bismuth should be the water-soluble form. In the prevention of relapse, chemotherapy combined with fever treatments was clearly superior — less than 0.5 per cent as compared with 13 to 18 per cent by other methods. It is imperative that treatment be continuous during the active stage to achieve the best percentage of good results, yet in the end there was 10 to 12 per cent of blindness from all methods. Apparently a tenth of the patients will be blind regardless of treatment. It was brought out that treatment during the inactive stage was of limited value in improving the final vision, but it should be noted that Klauder and Vandoren do not mean treatment to be dispensed with, since the patient still has congenital syphilis. It was stated that iodides have an unfavorable influence on the final

vision. In considering this paper, one should remember that all the work was done before the introduction of riboflavin. Cole<sup>39</sup> is now of the opinion that the combination of hyperpyrexia and large doses of riboflavin (vitamin B<sub>2</sub>) is the method of choice in the treatment of interstitial keratitis. He believes that other treatment should be withheld until the fever is terminated.

*Central-nervous-system syphilis.* Spiegel, Leifer and Sarason<sup>45</sup> have reported on the use of a new drug, Aldarsone, in neurosyphilis. This study extends over a period of five years and covers 133 patients with various types of the disease. Many of the patients received courses of bismuth injections concurrently, and fever therapy was given when indicated. The drug was well tolerated by the majority of patients, and no very serious reaction occurred. The results seem to indicate that Aldarsone is effective in neurosyphilis, and that optic atrophy is apparently no contraindication to the employment of this drug. This is encouraging, and if further work and longer periods of observation bear out these results, it will be a definite step in advance. Epstein and Solomon<sup>46</sup> stated that there are three factors relating to the mechanism of artificial fever: destruction of treponemes by elevation of body temperature, biologic response to nonspecific foreign protein, and alterations produced in the brain parenchyma by the malarial organism. If one grants these three factors, one is still somewhat at a loss to assess their relative importance. Epstein and Solomon have considered fever therapy in general and its effect on the various forms of neurosyphilis. The main point is their plea for the use of fever therapy in the treatment of asymptomatic neurosyphilis, since "accumulated clinical evidence indicates that fever therapy adequately prevents clinical neurosyphilis." This statement is made with the reservation that fever therapy is not so effective in juvenile paresis. A five-year comparison of artificial fever and therapeutic malaria was reported by Ewalt and Ebaugh.<sup>47</sup> Two hundred and thirty-two cases were equally divided without selection. All the malaria cases and 66 per cent of the artificial-fever patients were followed for five years (or until death). Remission or improvement occurred in 69 per cent of the fever group and in 58 per cent of the malaria group. It must be stated that the former underwent consistently higher temperatures. The authors raise the possibility that these higher temperatures are responsible for better results and suggest that the better physical condition of the fever patients at the end of treatment may be significant. Malarial therapy and artificial fever are not available in many institutions, however,

and several other methods of producing fever have been suggested. Kulchar and Card<sup>48</sup> report the use of typhoid "H antigen" vaccine, which eliminates the objectionable features of the old vaccine. One hundred and eighteen cases of various types of neurosyphilis were treated, and 94 were followed for periods of four to forty-six months. Most of these patients had previously had some chemotherapy. The symptomatic and serologic improvement compared favorably with the results of other forms of fever treatment. Kulchar and Card believe that the present method has a number of advantages in that fever can be produced, carefully controlled, and terminated as desired. It is stated that the relatively slight amount of constitutional reaction accompanying the fever makes it applicable with safety to many patients unable to receive other forms of fever treatment.

**Massive-dose therapy.** Reference has been made to this subject in previous progress reports, with emphasis on the fact that, although promising, the procedure must continue to be an experimental method for some time and should be used only in hospitalized cases under close observation, limited to cases of early syphilis, and employed only in well-equipped universities and syphilis centers. This opinion is echoed by Shaffer,<sup>49</sup> who calls attention to the fact that the method is now being tried in eight states under the supervision of the United States Public Health Service.<sup>50</sup> The instigators<sup>51</sup> of this procedure have continued its use with the substitution of Mapharsen for neoarsphenamine. Three hundred and eighty-two cases have been treated in all (neoarsphenamine and Mapharsen). There were significantly fewer reactions in the Mapharsen series. Including 15 re-treated cases, satisfactory results were attained in all respects in 88 per cent of the patients. There was 1 death, and 1 case showed a positive cerebrospinal fluid. There were 5 per cent of irreversible failures, but this figure might have been reduced if re-treatment had been attempted throughout. A committee representing the original group and the United States Public Health Service<sup>52</sup> evaluated all available data of the work so far accomplished. It includes thirteen large hospital clinics in nine cities. All the work reported was done with Mapharsen, and nearly all the serologic study was carried out in one of two laboratories. Nine hundred and sixty-eight cases of early syphilis were treated. Both sexes were included, but no pregnant women were treated. The results were satisfactory in 85 per cent of the cases. Toxicologic manifestations were comparatively mild. Adding these to all cases reported

in the literature from all sources, there have been 5 deaths (0.3 per cent) in 1600 patients. Apparently, the continuance of this study in well-organized centers is warranted. In the discussion of this paper, several authorities warned against release of the technic for general use. Cole<sup>53</sup> advocated conservatism and stated that he knew of several as yet unreported deaths. In his opinion, this treatment is still very much in the experimental phase. Elliott,<sup>52</sup> in closing the discussion, stated that some similar form of therapy may evolve to provide better results (and, it is hoped, fewer untoward results) than the treatment schedule in use at present. A modification of the massive-therapy program has already been reported by Schoch and Alexander,<sup>54</sup> who employed a multiple-dose, syringe-technic treatment schedule that utilizes injections twice a day. The series is small and the time of study is short, but all things must have a beginning, and Schoch is possibly on the right track.

CASE 28031

## PRESENTATION OF CASE

A thirty-nine-year-old linotype operator was admitted to the hospital because of disorientation and various motor weaknesses following a complicated illness.

He was in good health until seven months before entry, when he had a "cold," associated with generalized aches and pains. This was followed by a brief spell of intense pain in the left lower quadrant of the abdomen, with radiation to the lumbar region. There were no associated urinary symptoms. The temperature was not noted. At the same time, there was gradual onset of constipation; this was significant because the patient had always had very regular bowels. After a month, he had another "cold," accompanied by generalized malaise and pain in the left lower quadrant, radiating to the lower left side and back. His physician, who reported a urinalysis as negative, diagnosed "kidney stone" and gave no treatment. In the next two or three months, the patient noted increasing nervousness and restlessness, particularly at night. He had to stop work because of intense, persistent pain in the back. He lost appetite and began to lose weight, dropping about 50 pounds in the period before entry. Two months before admission here, he entered a New York City hospital, where he was told that he had pus in the urine and, following cystoscopy, that "an abscess of the left kidney was drained." After the cystoscopy, he passed clots of blood in the urine. The bladder was washed out several times. After the patient left the other hospital, the pain in the back still persisted. He felt "warm" on several occasions; however, it is not known whether he had actual fever. At about this time, he became quite "nervous and jittery." A local physician gave him some sort of sedation, as well as light and diathermy treatment to the back, and a calcium preparation intravenously. About four weeks before entry, vision became hazy, and it was noted that there was occasional lateral deviation of the right eye. The patient began to complain of pain in both ears and of throbbing, generalized headaches. He became increasingly slow in his reactions, and seemed

somewhat dazed, although rational. The left leg appeared to drag slightly when he walked. It is not known whether the leg was weak or whether he simply favored the leg because of pain in the left side of the back. Three weeks before entry, he motored some two hundred miles to Boston, thinking that the change in surroundings might benefit his nervousness. A few days after he arrived in Boston, a physician who was called because of excruciating back pain told the family that the liver was enlarged and the blood pressure normal. At night, twelve days before entry, the patient was suddenly found to be breathing stertorously. The mouth was pulled to the right side, there was paralysis of the left arm, and he could not speak. The next day, he was taken to another physician, who found that the left arm and left side of the face were paralyzed, and that the patient was unable to speak clearly. The blood pressure was 170 systolic, 90 diastolic. The patient then entered another hospital. After several days, there was some improvement in speech, but he remained disoriented. A lumbar puncture at this time showed that the pressure, cell count and protein were within normal limits; the Wassermann and gold-sol reactions were negative. A roentgenogram of the skull was negative. Three days before entry here, neurologic examination showed the patient to be disoriented, with a left central facial paralysis, left-sided weakness of the tongue, paralysis of the left vocal cord, weakness of the right arm and leg, and a questionable right Babinski plantar response. He was transferred to another hospital, with a diagnosis of thrombosis of the posterior inferior cerebellar artery. On arrival at that hospital, a small amount of bleeding from an old perforation of the left eardrum was noted. Physical examination was negative, except for the findings of a moderately soft, movable lymph node, measuring about 3 by 1.5 cm. in the right axilla, and a sharp, irregular, palpable liver margin. The blood pressure was 194 systolic, 104 diastolic. The temperature was 98°F. Neurologic examination was essentially as noted in the other outside hospital, with the addition of a possible right hemianopsia. Examination of the blood showed a red-cell count of 4,620,000 with 81 per cent hemoglobin, and a white-cell count of 18,450 with 68 per cent polymorphonuclears and 16 per cent band forms. The nonprotein nitrogen was 38 mg. and the serum bromide 6 mg. per 100 cc. The sedimentation rate was 32 mm. in two hours. A spinal tap gave clear fluid under an initial pressure of 120 mm. of water. There was good response to compression of the right jugular vein, but no response to

compression of the left. The fluid showed one polymorphonuclear and four red cells per cubic millimeter. The protein was 34 mg. per 100 cc. The Pandy, gold-sol, Hinton and Wassermann reactions were negative. Roentgenograms of the lumbar spine and of the skull, including special mastoid films, were all negative. Two days later, the temperature was 100.8°F. rectally and appeared to be rising. The patient was transferred to this hospital for possible surgical intervention.

The family and the remote past histories were irrelevant, except that the patient had had "ear trouble" in infancy, and had had chronic drainage from his left ear on many occasions in childhood and in later life.

On admission to the hospital, the patient was somewhat emaciated and delirious; he thrashed about in bed and talked incoherently. There were several, apparently self-inflicted, abrasions on the left foot, and the nail of the right great toe appeared recently avulsed. There were forced movements of the eyes to both sides, more especially to the left. There was suggestive left facial paralysis. The right arm and leg were less active than the left, but were no longer paralyzed. The reflexes were essentially normal. The fundi did not seem abnormal. The heart was not enlarged, and the sounds were of good quality, without murmurs. The aortic second sound was louder than the pulmonic second sound. The liver edge was sharp and firm, one fingerbreadth below the costal margin.

The temperature was 101.5°F., the pulse 132, and the respirations 20. The blood pressure was 175 systolic, 85 diastolic.

Examination of the blood showed a red-cell count of 4,450,000 with 80 per cent hemoglobin, and a white-cell count of 22,750 with 82 per cent polymorphonuclears. The nonprotein nitrogen was 24 mg., the serum albumin 5.4 gm. and the serum globulin 2.1 gm. per 100 cc. The carbon dioxide combining power was 27 vol. per cent, and the chlorides 95.3 milliequiv. per liter. The bromide level was 0.

On the second hospital day, a few brownish petechial spots were noted on the skin of the abdomen. These had not been present when the patient was examined in the outside hospital from which he had been last transferred. The questionable left facial paralysis had cleared. Paralysis of the right arm gradually appeared. The plantar responses were equivocal. On the third hospital day, the temperature rose sharply to 106°F. The patient became quite cyanotic and breathed with apparent difficulty. Dullness was noted in the right infraclavicular region, with palpable rhonchi.

There were scattered loud bronchial breath sounds and coarse and fine rales. A blood culture was taken, and sulfadiazine was started. Death supervened.

#### DIFFERENTIAL DIAGNOSIS

DR. WILLIAM DOCK\*: The occupation was probably not related to the rest of the story. I do not know what illnesses the operators of linotype machines have. On admission, the patient was disorientated, and I dare say his friends gave the complaint, which turns out to have been incorrect, for hazy vision a month earlier means that motor weakness for more than twelve days concluded an illness of seven months. He had a "cold," but we do not know what that means. The intense pain in the left lower quadrant may have been due to a renal stone, or to a diverticulitis. About this time, the patient was constipated; that does not mean anything localized in the large bowel, for with any sort of illness, episodes of constipation and anorexia are likely to occur. He had another "cold,"—I take it to be a febrile illness each time,—with chilly sensations and aching. Nothing is said about sneezing and running nose, and probably it was not an upper respiratory infection or cold in the ordinary sense.

The pain recurred and again was severe, and from this point on his personality went to pieces, with nervousness and restlessness, and he stopped work because of intense pain in the back. He lost appetite and 50 pounds of weight in the following month. The pain may have been renal colic; it may have been due to retroperitoneal tumor, involving the nerve roots, but remission in such cases is rare. It may have been due to disease in the vascular bed behind the peritoneum, a mycotic aneurysm or some other vascular lesion. I remember one case of brucellosis in which the presenting complaint was severe backache, which was due to mycotic aneurysm.

Now the story becomes murky. After cystoscopy, the patient passed blood clots in the urine. The examiners may have opened up a perinephritic abscess with the urethral catheter, and may actually have encountered an abscess in one of the pyramids and removed pus, but that sounds improbable. After that, there was some washing out of the bladder, but the pain in the back was unaffected. I do not believe, then, that the pain in the back was related to the alleged kidney abscess.

The personality became worse and worse, and the patient was hard to live with. When put on

\*Professor of pathology, Cornell University Medical College, New York City.

sedative treatment and intravenous therapy, he developed motor weakness for the first time: the vision became hazy, and he had lateral deviation of the right eye. I assume that he had diplopia and wonder if he had intracranial disease—either a vascular lesion, tumor or abscess.

The patient had severe pain in both ears and headache, so that we think more of tumor than of vascular disease. He became slow in his reactions, was somewhat dazed, and had trouble with the left leg. The deviation of the right eye makes us think of a left-sided lesion in the temporal region, whereas the trouble in the left leg should have come from a lesion on the other side.

Even the trip to Boston does not seem to have relieved the symptoms. The pain grew worse, the liver was found to be enlarged, and the blood pressure was normal at this time. The liver makes us think of tumor, with metastases. The patient was found with stertorous breathing, and had palsy on the left side, including the face and the left arm. The blood pressure was higher—the blood pressure may be elevated by intracranial tumor or intracranial disease acting as tumor. Soon, the patient seemed better, but was still disorientated. Lumbar puncture was negative.

Now we get into more trouble. There was left facial paralysis, with weakness of the right arm and leg, so that we must put the lesion below the tentorium to give a crossed palsy.

The patient entered this hospital, where he remained, and we have a series of examinations—all done by the same people, apparently. Here for the first time is noted evidence of an old otitis media, which makes us think more of abscess than of tumor. A movable lymph node in the right axilla was found; this may or may not have had anything to do with the case. At this time, the liver was sharp and irregular. If it was irregular, the patient must have had cirrhosis or tumor, but the observation may not have been correct. The blood pressure was still high, which makes us think of vascular disease. The sudden onset of hypertension with this sort of story is characteristic of diseases like periarteritis nodosa. But, so far, there is nothing else to go with it. The temperature was only 98°F. There was a possible right hemianopsia. How one can tell about that with any degree of accuracy in a disorientated patient, I do not know. Perhaps, on that day, he was not so disorientated. He had rather marked leukocytosis, with normal blood nonprotein nitrogen, and his troubles were not due to bromidism, with only 6 mg. per 100 cc. in the blood, which is very low. These neurologic findings certainly cannot be accounted for by sedation. The high leukocytosis and the sedimentation rate suggest

tumor, with much necrosis or infectious disease, such as abscess or periarteritis.

We come to the most striking thing in the history, for, if correct, it gives definite localization of the lesion. There was good response to compression of the right jugular vein but no response on the left. If that observation is correct, we can build up a whole diagnosis on it. However, it may be a historical landmark; he might have had lateral-sinus thrombosis early in life and been left with this. On the other hand, it may explain the whole business. The two bouts of "cold" might have been exacerbations of petrositis, with a jugular thrombophlebitis, followed by some sort of embolic lesion occupying the temporal fossa on the left side. If the patient had petrositis, he apparently had no meningitis with it. The spinal-fluid protein content was low, and the roentgenograms, including the special mastoid films, were negative. If that rules out petrositis as well as mastoid disease, I do not know what to do with the old otitis media and apparent obstruction of the jugular vein on the same side.

At last, the temperature began to rise. If the patient had periarteritis all this time, I think he should have had fever on previous occasions; but that is not necessarily so. The ear trouble is stated to date back to infancy, and he had had trouble of that sort off and on all his life. It may be that he had petrositis and extension of inflammation to the jugular bulb without any marked bone destruction, but it is not a helpful thing that the one syndrome that would be diagnostic—the Gradenigo syndrome (facial pain and sixth-nerve palsy due to petrositis)—is missing. The only sign of eye trouble was presumably the third nerve on the opposite side—nothing very helpful there.

When he came into the hospital, the patient still had left facial paralysis, and the right arm and leg were paralyzed and weak. The fundi were not abnormal, which certainly means that there was no malignant hypertension. It does not rule out periarteritis nodosa, however. The heart was not enlarged. There were no abnormal findings except that the liver edge was sharp and firm one fingerbreadth below the costal margin. If he had had chronic suppurative disease for years, he might have amyloid.

We then have some assorted findings: the temperature was higher, the blood pressure was still high, and the patient had marked leukocytosis but a normal blood nitrogen. The carbon dioxide combining power and the chloride values were a little on the low side, which will not help our diagnosis, and there was no bromide in the blood.

What astonishes me is that on this man, who had intracranial complications of some sort, no

chest plate was taken. The first thing we think of with a man with something in his head is to rule out bronchiogenic carcinoma.

DR. GEORGE W. HOLMES: We have a chest plate, which does not seem to have been reported. The interesting thing is this increase in the supracardiac shadow. The shadow has a very sharply defined margin and apparently extends under the clavicle, but I do not believe it reaches the apex. It seems to me that there is a lesion extending from the sternal notch to the region of the lung root. There is no evidence of disease of any kind in the lungs.

DR. DOCK: Do you think it could be a sulcus tumor?

DR. HOLMES: It could be, but I doubt it; there is not enough in the apex. It apparently does not extend into the pleura. It may extend across the mediastinum. It has the somewhat caplike shadow that one sometimes sees in certain tumors of the mediastinum. There is no enlargement of the heart shadow, and the heart looks perfectly normal in shape. The aortic knob is probably normal, and there is no erosion of the ribs, so that I do not believe that there is congenital anomaly of the heart or great vessels. So far as I can tell from this plate, which did not have quite enough exposure, there is no compression of the trachea or of the bronchi. A mass of lymph nodes in that region might look like this, but the shadow is smooth on the outside border, not lobular as a shadow due to glands would be. In addition, there is a high diaphragm on the right side, and the liver appears large.

We have pretty good evidence that the petrous tip is normal—no tumor in the internal auditory canal, and a normal mastoid region. It is rather unusual to have disease of the petrous tips without disease of the mastoid process. All the evidence we have in the skull is quite convincingly negative.

DR. DOCK: One other thing surprises me: we have all these milliequivalent levels in the blood, but there is no report of urine examination. The only reason I am interested in the urine at the moment is that if the patient had periarteritis or if the liver enlargement were due to amyloid, he might have had protein in the urine. I do not know what to do with the shadow in the mediastinum. I am sorry I asked for that chest plate.

DR. CHARLES DERRICK: The urine was not recorded because the patient was incontinent.

DR. DOCK: Then we shall not know about that. Perhaps it is not important.

When we talk about diseases that begin in the lower quadrants, causing pain and enlarged livers,

mediastinal shadows and intracranial lesions, we think among other things of a tumor beginning in the testis. I should like to know whether this patient had testes in the scrotum. He had been to a urologist and five physicians—I suppose that is known.

DR. TRACY B. MALLORY: The testes were in normal position.

DR. DOCK: Tumor beginning in an undescended testis sometimes gives pain in the belly, frequently metastasizes to the brain, and there causes very rapid changes of psyche and motor signs, not lasting over months, but a few days as innumerable intracranial metastases begin to go to pieces; but here there is no evidence of that type of tumor.

We come back to this man, who was rapidly deteriorating mentally, who had had numerous other signs of cerebral involvement, most of which cleared up, but whose paralysis of the right arm proved lasting and who died with a high temperature, 106°F. It seems high for any sort of sepsis and suggests that the intracranial lesion might have encroached on the hypothalamic region. My guess in this case, before knowing about the chest x-ray films, was based on the assumption that he had some disease of the left jugular vein. If we accept that (and I must admit that it is a gamble), the case was one of chronic otitis media, without much damage in the mastoid or petrous bone, but with extension of inflammatory disease to the jugular bulb and, finally, brain abscess. The lesion in the belly that caused the pain, whatever it should turn out to be, and these things in the brain may all be hematogenous metastases or suppuration due to organisms of very low virulence that had entered from the otitis media. Thus, I should guess chronic brain abscess, presumably in the temporal lobe, which seems the most likely region for this process. I do not know whether to put it on the right or left, but because the patient had more disease on the left we might put it there. He may have had terminal septicemia or meningitis.

But the chest x-ray film shows the liver to be so enlarged that it makes us think of tumor, and in the end all this nicely built-up story will go to pieces and we shall find that tumor, with a good deal of necrosis, caused the trouble. This would explain the shadow in the mediastinum: that is, tumor in the mediastinum, tumor in the liver and retroperitoneal tissues and intracranial metastases. I do not know how else to account for the enlarged liver. It seems incredible that the patient would have so many abscesses in the liver as the result of septicemia, and I am therefore hesitant

to account for the huge liver on that basis. The mediastinal shadow could also be accounted for by sepsis. Perhaps he also had a suppurative lesion along the vertebrae in the mediastinum.

Just to be consistent and to stick to the observation concerning the left jugular vein, I make my guess that that is where the trouble started, but admit that the whole thing may turn out to have been due to a neoplasm.

DR. JOST MICHELSEN: With brain abscess, how do you explain the cerebrospinal findings—the low pressure, the low protein and so forth?

DR. DOCK: The spinal fluid could be quite normal if the abscess were deeply placed in the brain. It seems to have been well walled off. Furthermore, a temporal-lobe abscess may have quite normal spinal fluid.

DR. MICHELSEN: In the acute stage?

DR. DOCK: Have we evidence that it was acute? The patient had fever only at the end. These varying palsies suggest an abscess, which does not actually destroy anything but from time to time causes disturbances that may be associated with edema or something of that sort. That is a long chance, but this is a puzzling case.

DR. JAMES B. AYER: I know the case, but I think you put too much stress on the left jugular compression.

DR. DOCK: So do I, after seeing the x-ray film of the chest.

DR. AYER: That may be normal. I think it was too bad it was in there.

DR. DOCK: I think it was good, because it gave me a point to build on.

DR. G. COLKET CANER: One of the striking points was the loss of 50 pounds early in the illness before any fever was reported; this seems to suggest neoplasm, much more than an infectious process, but I should not know where it started.

DR. DOCK: Weight loss may be marked with intracranial disease and with change of personality. One of the problems, if you try to explain this on the basis of neoplastic disease, is that the cerebral symptoms came and went. I should expect cerebral metastases to give progressive symptoms rather than transient ones.

DR. AYER: Not infrequently, metastases give changing symptoms.

DR. WYMAN RICHARDSON: May I ask if the shadow in the mediastinum looks like the thyroid gland?

DR. HOLMES: It could be.

DR. RICHARDSON: Might not a tumor originating in the thyroid gland metastasize to bone, explaining backache, and later metastasize to the brain?

DR. DOCK: X-ray films of the spine were negative. With thyroid metastases to the spine, I think that one would pick them up three months after the pain started.

DR. HOLMES: I agree.

#### CLINICAL DIAGNOSES

Brain abscess?

Right-upper-lobe pneumonia.

#### DR. DOCK'S DIAGNOSES

Chronic otitis media.

Jugular thrombophlebitis.

Metastatic abscesses, paravertebral and cerebral.

#### ANATOMICAL DIAGNOSES

Carcinoma of the tail of the pancreas, with metastases to regional nodes, liver, lungs and pleura.

Endocarditis, probably marantic: aortic valve.

Multiple emboli, with secondary infarction, to brain, spleen and kidneys.

Emboli in portal vein.

Infarction, partial, of liver.

Perforation of left eardrum.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: At post-mortem examination, we found an enormous liver, full of metastases. The next finding was a large mass, which completely filled the lesser peritoneal cavity and evidently arose from the tail of the pancreas and had secondarily involved the stomach and the colon. There were pulmonary metastases, and the shadow in the x-ray film arose from lymph nodes in the neighborhood of the trachea. When we opened the heart, we found an acute endocarditis of the mitral valve, apparently of the vegetative type. The brain showed embolic areas of infarction, but no tumor metastases. The endocarditis remains a problem. Grossly, it was suggestive of acute bacterial endocarditis. Blood cultures taken the day before death and at autopsy, however, were sterile. Attempts to culture the vegetations themselves provided us with a healthy growth of non-hemolytic streptococci, colon bacilli and *Bacillus subtilis*. One can take one's choice or discard them all. The sections of the heart valve showed no bacteria whatever, and practically no inflammatory reaction. It seemed to be a perfectly pure thrombotic vegetation, with no inflammatory reaction, and no fibrosis or organization at its base. A further complication in the interpretation was provided by finding one really good Aschoff nodule in the myocardium, so that what kind of endocarditis this was, I do not know. We have

no proof that it was bacterial. It does not in itself look rheumatic, but the Aschoff body suggests that etiology. Moreover, I do not like the idea of rheumatic vegetations that throw off multiple emboli. Whether there is such a thing as marantic endocarditis, I have never been certain. This case may be so classified if one believes it to exist. At all events, it is by no means rare for patients dying with metastatic neoplasm to develop a terminal endocarditis. It is comparatively uncommon for this to produce multiple infarcts of significant size. There were infarcts in both spleen and kidney, quite fresh ones. There was no evidence of old abscess or stone in the kidney.

DR. DOCK: Were the lateral sinuses and the jugular vein all right?

DR. MALLORY: Yes; there was only a perforation in the left ear drum, and no mastoiditis.

Finally, a most unusual condition, which probably played no part in the symptomatology, was found in the portal circulation. A thrombus had formed in the splenic vein, where it was involved by the tumor of the pancreas. From this, fragments had broken off and had been swept as emboli into the portal circulation, where they were found in the intrahepatic portal radicles. Partial or incomplete infarction of many focal areas in the liver had resulted, although the hepatic arteries had, of course, prevented complete infarction.

## CASE 28032

### PRESENTATION OF CASE

A sixty-three-year-old housewife was admitted complaining of shortness of breath.

For sixteen years, she had had diabetes, which was controlled by diet in addition to 10 units of insulin daily. The insulin therapy, however, was stopped, one year before entry, on the advice of her physician. Three months before admission, while the patient was pumping water, a sudden, severe, oppressive crushing pain occurred beneath the lower sternum and radiated straight through to the back and down the inner aspects of both arms as far as the elbows. She became anxious, extremely short of breath and covered with perspiration, and the heart beat rapidly. Rest gave no relief. The patient did not mention the pain to her family, but went in to supper, after which the pain became worse. Nausea and vomiting developed, and she called her physician, who put her to bed. The pain, however, remained unchanged for two days, after which it disappeared. The patient remained in bed for two weeks, but was afterward dyspneic on slight exertion. Two

weeks before admission, she became orthopneic, at first being able to sleep on two pillows, then unable to sleep except when she sat almost straight up in a chair. During the night, she had several attacks of waking with a sense of suffocation and gasping for breath for about ten minutes. Four days after the appearance of orthopnea, the ankles began to swell, the edema gradually extending to the knees.

For many years, the patient had had brief attacks of precordial pain frequently radiating down the arms; there was no history of rheumatic fever, hypertension or weight loss. For several years, she had had occasional attacks of sharp squeezing pain beneath the right costal margin lasting two to ten minutes and associated with a slight swelling in that area. The pain and swelling were relieved by the taking of food. Twenty-eight years prior to admission, she had an enucleation of the right eye for glaucoma.

Physical examination revealed a pale, poorly nourished, slightly cyanotic woman sitting up in bed, with dyspnea, and complaining of substernal distress. There was marked pitting edema of both lower legs and of the sacrum. A deep 2-cm. scar was present on the sole of the right foot. The right eye was absent. The left eye was myopic, but examination of the pupil was negative. There was vacuolar degeneration of the lens. The disk was flat and showed a myopic crescent, and scattered about it were hemorrhages and exudate. External ocular movements were normal. The patient was edentulous and had a coated tongue. The tonsils were buried. The chest was somewhat barrel shaped, expansion was limited, and the accessory respiratory muscles were used extensively. There was dullness to flatness, with decreased breath sounds and moist rales, at both bases. The diaphragm was high, with limited excursion. The heart was enlarged to the left, but could not be outlined by percussion. The point of maximum intensity was felt 1.5 cm. to the left of the mid-clavicular line. Retromammary dullness was increased. The sounds were of good quality; there were no murmurs, and the rhythm was normal. The peripheral vessels were tortuous and sclerotic. No pulsations could be made out in either dorsalis pedis or posterior tibial arteries. Reflexes could not be obtained in the lower extremities, and there was impaired vibratory sense in both legs. Examination of the abdomen was negative.

The rectal temperature was 100°F., the pulse 98, and the respirations 20. The blood pressure was 130 systolic, 80 diastolic.

Examination of the urine showed a specific gravity of 1.022, a ++ test for albumin, a + test for

sugar, and an occasional red cell, 30 white cells and an occasional hyaline cast per high power field. The blood showed a red cell count of 4,260,000 with 74 per cent hemoglobin, and a white-cell count of 9500 with 60 per cent polymorphonuclears. The serum nonprotein nitrogen was 28 mg and the protein 5.6 gm per 100 cc. The fasting blood sugar was 374 mg per 100 cc. A blood Hinton reaction was negative.

On the night of the day of admission, the patient complained of slight substernal oppression. At 5 o'clock the following morning, she seemed unusually drowsy and at 6 o'clock could not be roused. There were signs of an early left sided hemiplegia. The heart sounds were poor, and the blood pressure 70 systolic, 40 diastolic. The respirations were shallow and weak. The rectal temperature was 103°F, the pulse 80, and the respirations 35.

The patient rapidly failed and died on the third hospital day. A short while before death, an electrocardiogram showed a PR interval of 0.16 second, a ventricular rate of 100 and normal rhythm. The ST intervals in Leads 1 and 2 were depressed, and those in Lead 3 were elevated. There was moderate left axis deviation.

#### DIFFERENTIAL DIAGNOSIS

**DR PAUL D WHITE** Dyspnea was this patient's chief complaint.

We have shown in the last year or two, in association with Dr. Howard F Root,\* that coronary heart disease is much commoner in diabetic than in nondiabetic patients.

It is a little unusual for pain to radiate through to the back in acute coronary occlusion.

It is not likely that the rapid beating of the heart was responsible for such terrific pain as that described here. That is probably a secondary symptom due to the pain or whatever caused the pain, and not the primary cause of the pain itself. Persons who have coronary insufficiency may develop severe pain, but hardly of this severity, when they have paroxysmal tachycardia. It is not likely that the perspiration was due to apprehension alone. This patient was sturdy, and could stand pain and did not want to give in to it.

I should like to be sure that nausea and vomiting developed before and not after medication. Did the physician give her morphine?

**DR BENJAMIN CASTLEMAN** There is a letter from her doctor stating that digitalis was given; there is no suggestion that he administered morphine.

**DR WHITE** The pain gradually subsided. Two weeks in bed is a short time for any episode as severe as this. That may indicate an unusually rapid recovery, or may have been due to refusal on her part to stay in bed more than that length of time. Whatever happened was followed by the appearance of dyspnea on slight exertion, which suggests that the patient got up too soon.

Three months after the onset of the acute illness, she became orthopneic, which means a progression of the dyspnea.

She had right sided heart failure rapidly following extensive left-sided heart failure; that can be the only interpretation of this sequence of events. That the painful episode was what set off the congestive failure, we cannot be absolutely certain, but it looks so.

"For many years, the patient had had brief attacks of precordial pain frequently radiating down the arms." This suggests that she had been somewhat ailing for a long time but apparently not enough so to consult a physician. I should like to know more about the attacks of precordial pain. The precordium is quite extensive, and there is a good deal of difference in clinical significance between substernal pain and that at the cardiac apex or left breast part of the precordium. The story sounds like angina pectoris, probably on effort.

"For several years, she had had occasional attacks of sharp squeezing pain . . . The pain and swelling were relieved by the taking of food." That suggests hyperacidity and cardiospasm, a definite digestive disorder.

"Physical examination revealed a pale, poorly nourished, slightly cyanotic woman sitting up in bed, with dyspnea, and complaining of substernal distress." I have mentioned before that patients with dyspnea usually do not have substernal distress—in short, that they do not have myocardial and coronary insufficiency at the same time; hence the substernal distress may have been due to cardiospasm or other noncardiac causes.

"Retromammary dullness was increased." This is important if true. Of course, marked increase in retromammary dullness suggests aneurysmal dilatation of the aorta in a cardiovascular patient. "There were no murmurs, and the rhythm was normal." This statement is very important in ruling out valvular disease.

The blood pressure was normal, there is no suggestion of hypertension. Apparently there was not a drop from a high blood pressure.

"The peripheral vessels were tortuous and sclerotic. No pulsations could be made out in either dorsalis pedis or posterior tibial arteries." In dia-

\*Root H F, Bland E F, Gordon W H and White P D. Coronary atherosclerosis in diabetes mellitus: a postmortem study. *JAMA* 113: 30, 1939.

betic patients, one may find an obliterating sclerosis, which could cause these signs.

We can now begin to build up a story for a dissecting aortic aneurysm, with sudden anterior chest pain referred to the back, increase in retro-manubrial dullness, and absence of pulsations in the feet.

"The temperature was 100°F." There may be slight fever due to congestive failure alone without the need of making an additional diagnosis of infarction or infection anywhere, but there is usually some complication in febrile patients with congestive heart failure to explain the fever.

Left-axis deviation is the most significant finding in the electrocardiogram. Nevertheless, change in the ST intervals may also be of some consequence.

In summary, we know that this patient had diabetes. She had extensive and severe arteriosclerosis, including the coronary arteries and probably the aorta. She had cardiac enlargement and failure. These things are quite clear. The points in doubt are the cause of the acute attack three months before she died and the cause of the final episode. It is too easy to diagnose myocardial infarction as explaining both, but nevertheless,—because it is most probable, even though too easy,—I shall give that as my first diagnosis, realizing that I am not at all sure of being correct. Dissecting aneurysm is a possibility. A dissection of the aorta is commoner in a person who is hypertensive, but it is not limited to hypertensive patients. It is conceivable that both conditions could be present in a patient of this sort, with a high degree of coronary-artery damage and secondary myocardial effects from it. Whether that is the only condition to be found is open to some doubt. Sudden intense pain radiating to the back, with the cutting off of the circulation to the feet, is strongly suggestive of dissecting aortic aneurysm, but the faulty peripheral circulation may be secondary to diabetic sclerosis of the vessels. The patient had had some indigestion. It is quite common for gallstones to be associated with coronary-artery disease, so that I should not be surprised if gallstones were present in this patient, although they were probably not responsible for the original severe attack of pain. Nausea and vomiting are commoner with gallstone colic than with attacks of coronary thrombosis, but once in a while an attack of biliary colic precipitates heart failure in a patient who has a good deal of heart disease to start with. I do not believe, however, that a digestive upset could explain the original attack. I should vote for the probability of myocardial in-

farction in general, but admit the possibility of a dissecting aortic aneurysm.

A PHYSICIAN: How about the terminal event?

DR. WHITE: I should think that a fresh infarction could explain the terminal event, although if there had been a dissecting aortic aneurysm to explain the first episode, rupture of the aorta could account for the final illness. A cerebrovascular accident may also have occurred. It does not seem likely that the final episode was diabetic coma per se. I do not know whether it is possible to have hemiplegia due to diabetic coma complicating severe cerebral vascular disease without complete occlusion of a vessel. I cannot say whether fresh coronary thrombosis was the cause of death, but I think it was.

DR. HOWARD B. SPRAGUE: Do you think she might have had mural thrombus with embolism?

DR. WHITE: I wrote it down as a possibility, but I do not consider it an essential diagnosis in a person with so much cerebrovascular disease.

DR. CASTLEMAN: Can you explain the hemiplegia solely on the basis of arteriosclerosis without thrombosis or embolism?

DR. WHITE: Yes; I think that I have been caught several times on terminal events of such a nature. In a similar way, abnormalities of the electrocardiogram can be explained by low pressure in a coronary circulation that is already at fault, without fresh coronary occlusion. Several times, I have diagnosed cerebral embolism in the presence of weakness on one side of the body or the other without finding such a condition at autopsy.

#### CLINICAL DIAGNOSES

Coronary occlusion.  
Cardiac failure.  
Generalized arteriosclerosis.  
Diabetes mellitus.  
Cerebral accident, with left hemiplegia.

#### DR. WHITE'S DIAGNOSES

Diabetes mellitus.  
Extensive arteriosclerosis, coronary, cerebral and peripheral.  
Coronary occlusion, with myocardial infarction, old and new.  
Congestive heart failure, left ventricular, followed by right.  
Hemiplegia due to cerebral vascular insufficiency.  
Dissecting aortic aneurysm, with terminal rupture?

## ANATOMICAL DIAGNOSES

Embolism of middle cerebral and posterior cerebral arteries, right and left.  
Cerebral infarcts, bilateral, recent.  
Coronary thrombosis, old.  
Cardiac infarction, healed.  
Chronic passive congestion of liver and spleen  
Hydrothorax, ascites and peripheral edema.  
Arteriosclerosis, generalized, marked.

## PATHOLOGICAL DISCUSSION

DR CASTLEMAN: This patient was in severe failure, as shown by a liter of fluid in the abdomen and as much more in each chest cavity. The liver showed signs of chronic passive congestion. The heart weighed only 325 gm., was slightly dilated, and showed old myocardial infarction on the posterior aspect of the left ventricle and diffuse scarring throughout the myocardium. That was confirmed by microscopic sections, which revealed scarring in every microscopic field, a characteristic finding in almost every case of angina pectoris. All the coronary vessels were severely sclerotic—almost rigid tubes with extensive calcification. The left descending branch was completely obliterated by an old thrombus, and beyond it was another thrombus that was more recent, which would fit the episode of three months before entry. The orifice of the right coronary artery was almost completely covered by an atherosclerotic plaque, so that very little blood was getting to the heart muscle. No mural thrombus was noted. In the brain, there was an occlusion of the right middle cerebral artery beyond the openings of the lenticular striate branches, and

an infarct of the right parietal lobe to correspond to that distribution. The infarction was very recent, and the occluding thrombus or embolus looked older than the infarct. I believe that it was an embolus, and the fact that we also found two recent lesions in each occipital lobe is more evidence that the process was embolic. The source could not be determined, although there may have been a few tiny mural thrombi on the endocardium that were not noticed at the time of autopsy. There was severe arteriosclerosis of the aorta, but no dissection.

DR. WHITE: The slight substernal oppression that was complained of the night before the patient died may have been an attack of angina pectoris.

Did she have gallstones?

DR CASTLEMAN: The gall bladder was completely obliterated, apparently from old chronic inflammation.

Is it not true, Dr. White, that if a patient is in heart failure one would not expect a dissecting aneurysm?

DR. WHITE: Yes; but this patient was not in heart failure three months ago. The important point was the explanation of the pain at that time.

DR CASTLEMAN: Do any of the patients with healed dissecting aneurysm die in heart failure?

DR. WHITE: I believe that, in a heart so seriously involved as this, one would prefer the initial diagnosis of coronary heart disease with angina pectoris, but the severe shock of a dissecting aneurysm might precipitate heart failure.

## WAR AND VENEREAL DISEASE

THE country is at war. For ultimate victory, among other items, the fighting services must have not only planes, guns and tanks, but proper food and good health; and of the factors causing disability among soldiers and sailors no one has been more important than venereal disease. As a complication of war, it has accompanied armies for centuries. Wherever armies have gone, the specter of venereal disease has stalked, and has immobilized manpower, often on a large scale. Today, the army camp, with its motorized equipment of modern warfare, is accompanied by the dangers of the trailer camp, as pointed out elsewhere in this issue of the *Journal*. And yet the past few years have indicated that much can be accomplished in the control of this scourge. If

one studies the curve of the venereal-disease rate of the United States Army over the last fifty years, one finds a gradual and striking reduction from a peak of approximately 160 per 1000 in 1902 to a low of about 36 per 1000 in 1939.<sup>1</sup> In England, the total venereal-disease rate in the army has steadily fallen, and for the first five months of 1941 was only 8.4 per 1000, with the ratio of gonorrhea to syphilis remaining about 8:1.<sup>2</sup> In this country, in two large maneuver areas where venereal-disease control has been studied, gonorrhea was about four and ten times as frequent as syphilis.<sup>3</sup>

The incidence of venereal disease among selectees has been surprisingly low, and of course, no person with an active case is admitted to the Army or Navy. Moreover, steps are being taken to control these diseases even more effectively than in the last war. Although the medical officers of the Army and Navy are responsible for the prevention and effective treatment of disease, they need assistance to fulfill the requirements of modern preventive medicine. Thus, in July, 1941, Congress passed the May Act, which provides for the control of prostitution in such areas around military and naval establishments as are designated by the Secretary of War and the Secretary of the Navy. The Federal Bureau of Investigation has been made responsible for the enforcement of this law.

In August, 1941, the Secretary of War, through the Chief of Staff, issued an order regarding the prohibition of prostitution within reasonable distance of military establishments. This order placed the responsibility for the health and welfare of personnel on the commanding officer of each post or camp and outlined the procedure of obtaining local co-operation for the remedying of bad conditions, as well as that to be followed if local co-operation failed. To achieve the full effect of the May Act, the commanding officer may obtain aid from both the Federal Security Agency and the Adjutant General of the Army.

In addition, on October 2, 1941, the Federal Security Agency established the Division of Social Protection, whose purpose is primarily to "promote the public health by the reduction of venereal

disease through the repression of commercialized prostitution." The United States Public Health Service and the Defense, Health and Welfare Services are likewise under the Federal Security Agency, and both have departments dealing with venereal disease, as well as other health conditions. Furthermore, the Army and Navy Committee on Welfare and Recreation, the American Social Hygiene Association and various other agencies are in a position to aid in various phases of the problem.

The machinery for the control of venereal disease and for the prevention of its resulting disability seems to exist, even with the very rapid expansion of the military and naval forces that is bound to occur in the present emergency. The full efficiency of this machinery, however, will be attained only by the proper co-ordination of the various agencies participating in this program.

### ACUTE INTESTINAL OBSTRUCTION

ACUTE intestinal obstruction is one of the major problems of any surgical service and contributes to a large number of deaths. For the last five years in Massachusetts, intestinal obstruction has annually accounted for an average of 4 deaths per 100,000 population. Of course, not all these deaths resulted from acute conditions, but many other deaths from acute obstruction were probably not included, being masked under such diagnoses as appendicitis and salpingitis. If seen in the first six to twelve hours, no patient should die from simple obstruction due to adhesive bands, from gallstone obstruction or from intussusception, and very few should fail to react favorably to treatment for most other types of obstruction if they are intelligently handled by the physicians who first see them. In the past, a difficulty has been the obscurity of the diagnosis, because of the lack of localizing or of pathognomonic symptoms in the early curable stage of the illness. The diagnosis has been based, in most cases, purely on the his-

tory and abdominal palpation, accompanied, all too frequently, by the time-consuming and exhausting therapeutic test of multiple enemas.

Aids have recently been developed that greatly simplify and standardize the early diagnosis of acute obstruction. The outstanding one is x-ray examination of the abdomen by the so-called "flat plate" or "scout plate." Such an examination does not trouble the patient and gives definite information very early in the condition. To be effective, however, hospitals must be organized so that such plates can be read promptly. A delay of several hours in making a diagnosis of acute obstruction largely negates the advantage afforded by x-ray films of this type.

In this issue of the *Journal* is a paper concerning another very much neglected aid to such a diagnosis. Abdominal auscultation has been used in a relatively desultory fashion for years, but few physicians or surgeons have paid enough attention to it to perfect their interpretation of abdominal sounds. Only recently have adequate discussions of this subject come into prominence in surgical texts. One of the best is by Wangenstein,<sup>1</sup> who states, in a section on the diagnosis of acute intestinal obstruction:

*Auscultation* — The chief value of auscultation in an acute intestinal lesion relates to the determination of whether *intestinal colic* is absent or present. The repeated audition of borborygmi with the stethoscope at the acme of the pain of which the patient complains establishes the pain as being caused by the intestinal contraction. To be certain, borborygmi or intestinal noises may be heard in other disorders, but it is the intimate time relationship between noise and pain which identifies its origin. A noisy abdomen does not therefore indicate the presence of a mechanical obstruction of the bowel, such a finding only denotes the state of activity of the intestine. A silent abdomen indicates absence of intestinal activity, a noisy abdomen without *intestinal colic* signifies that the bowel is hyperactive.

Other excellent statements concerning auscultation are found in Vaughan's<sup>2</sup> section on appendicitis and Ochsner's<sup>3</sup> section on acute intestinal obstruction in *Nelson New Loose Leaf Surgery*. However, Lewis and Fier,<sup>4</sup> writing on appendicitis in Christopher's *Text Book of Surgery*, do not mention auscultation, nor did Hertzler,<sup>5</sup> writing

on diseases of the peritoneum, and Cutler and Scott,<sup>6</sup> on postoperative complications, mention it in the somewhat older text, Graham's *Surgical Diagnosis*. In the latter book, however, Richardson,<sup>7</sup> in the section on the clinical manifestations of acute intestinal obstruction, makes the following significant statement, "On auscultation the gurgling due to hyperactive peristalsis is usually heard, a finding which is very useful in distinguishing mechanical from paralytic obstruction."

It should be noted that Wangensteen emphasizes a very important distinction in interpretation that is not made clear by Dr. Stevens, namely, that the loud and frequent sounds of hyperperistalsis mean hyperperistalsis—they do not necessarily mean obstruction. On the other hand, Dr. Stevens's courageous description of his three failures and one success should serve to teach others, who, like him, see such cases only rarely, concerning the possibilities in this field.

The interpretation of intestinal sounds, however, is not too simple and cannot be taught from a book or an article. There is a wide variation of intensity and frequency in relation to the physiologic state of digestion, with greater activity one or two hours after meals than at other times. It is imperative that each physician who is to use this diagnostic aid study normal intestinal sounds at all times of the day so that he can learn what is abnormal.

Another aid in intestinal obstruction is the Miller-Abbott or double-lumen tube. But this tube is used more to determine the location of an obstruction and to treat certain types of obstruction than to help in the original diagnosis. In particularly difficult cases in which a Miller-Abbott tube is thought to be near an obstruction, a small amount of thin barium may be introduced through it to outline the lesion. Ordinary barium examinations, however, should *never* be undertaken in the presence of acute or partial obstruction, since masses of barium are extremely difficult to handle if a resection is performed or if the intestine is opened for any purpose. If mineral oil happens to be mixed with the barium, as frequently occurs in these cases, a thick tenacious gummy mass is formed. Spilling of even a very small amount

of this mixture into the peritoneal cavity almost invariably results in a fatal peritonitis.

Acute intestinal obstruction, except in those cases in which strangulation takes place, seldom causes severe immediate pain; furthermore, the pain is not localized. Any new type of abdominal pain should be viewed with suspicion. After palpation, one should listen to the intestinal sounds, and then, if there is the least doubt about what is going on, an x-ray examination without barium should be performed. With this evidence, diagnosis is usually surprisingly easy and the results of treatment extraordinarily good, because patients with obstruction are cared for early—when they should be.

#### MEDICAL EPONYM

##### McBURNAY'S POINT

Charles McBurney (1845-1913) reported his "Experience with Early Operative Interference in Cases of Disease of the Vermiform Appendix" in the *New York Medical Journal* (50: 676-684, 1889) and described his famous point thus:

The *exact* locality of the greatest sensitiveness to pressure has seemed to me to be usually one of importance. Whatever may be the position of the healthy appendix as found in the dead-house—and I am well aware that its position when uninfamed varies greatly—I have found in all of my operations that it lay, either thickened, shortened or adherent, very close to its point of attachment to the caecum. This, of course, must, in early stages of the disease, determine the seat of greatest pain *on pressure*. And I believe that in every case the seat of greatest pain, *determined by the pressure of one finger*, has been very exactly between an inch and a half and two inches from the anterior spinous process of the ilium on a straight line drawn from that process to the umbilicus. This may appear to be an affectation of accuracy, but, so far as my experience goes, the observation is correct.

## MASSACHUSETTS MEDICAL SOCIETY

## STATED MEETING OF THE COUNCIL

A stated meeting of the Council will be held in John Ware Hall, Boston Medical Library, 8 Fenway, on Wednesday, February 4, 1942, at 10:30 a.m.

*Business*

- 1 Call to order at 10:30 a.m.
- 2 Presentation of record of meeting held October 1, 1941, as published in the *New England Journal of Medicine*, for November 6, 1941.
- 3 Report of Auditing Committee and of Treasurer
- 4 Reports of standing and special committees
- 5 Appointment of Delegates
  - (a) To the House of Delegates, American Medical Association, for two years from June 1, 1942
  - (b) To the annual meetings of the five New England state medical societies in 1942
  - (c) To the Annual Congress of the American Medical Association on Medical Education and Licensure at the Palmer House, Chicago, February 16 and 17, 1942
- 6 Such other business as may lawfully come before the meeting

MICHAEL A. TIGHE, M.D.  
Secretary

The president, Dr. Ober, requests that all councilors at attending the meeting remain until the business of the meeting is finished.

IMPORTANT ADDENDA TO BE CONSIDERED  
BY THE COUNCIL

## COMMITTEE ON PUBLIC RELATIONS

*Subcommittee on Tax-Supported Medical Care*

The special committee having this matter in hand will offer the following report:

**Medical Relief** Of the total bill for medical care nearly a quarter is now paid from tax revenues.

The quality of hospital medical care is effectively supervised by the professional staff. The quality of medical care to the indigents and old age recipients outside hospitals is too often below acceptable standards.

The Massachusetts Medical Society believes that it should endeavor to improve these standards and offers its services in the interest of better distribution of medical care in this field.

If the physicians of a given locality can agree among themselves to formulate and to participate seriously in a plan adapted to the medical needs and medical and economic resources of their community, the state laws and the regulations of the State Department of Public Welfare make it possible for the indigent patient to choose his own physician and for the physician to treat his own patients, with payment for his services supplied from public funds. Although the local public welfare official is responsible for providing necessary medical care for indigent persons the determination of medical needs should now be made with the advice of the medical profession.

All physicians should be encouraged to participate in this service.

For the purpose of maintaining orderly, practical and logical thinking on the subject of medical welfare policies, the following points must be kept in mind. Under various Massachusetts laws local welfare officials are empowered to provide medical care on a salary basis or on a fee for service basis, consequently, the indigent patient may or may not have the right of free choice of physicians, according to the procedure adopted in any given locality. In addition in cases which receive reimbursement from the State their local welfare departments must be operated under the rules and regulations promulgated by the State Department of Public Welfare. It should also be noted that the local welfare official is legally responsible to his community and to the State, for the entire conduct of his department, and he can neither delegate nor share this responsibility. He can seek and accept advice or suggestions concerning medical problems and procedures, but in the final analysis responsibility for all decisions rests solely on him.

The State Department of Public Welfare now has a full time medical adviser, and he in turn has a medical advisory committee (selected from a group nominated at his request by the Massachusetts Medical Society).

**Free Choice of Physician** The State Department of Public Welfare points out that under the law it cannot guarantee free choice of physician but draws attention to the fact that whereas in some localities it has been long standing practice to employ salaried doctors, introduction of a new medical plan has had a tendency to increase consideration of the use of the fee for service basis, since provision is made for local medical controls. The department approves the principle of free choice and is endeavoring to extend its practice.

In the majority of communities of this state (about 67 per cent), a system of free choice of physician on a fee for service basis is used by the local welfare agency. However, the department has neither the power under the law, nor does its experience to date indicate the need, to mandate communities to the extent that they must use the fee for service system rather than salary or contract. It is the major responsibility of the department to see that the scope of the program provides adequate service of high quality at reasonable cost to the taxpayers. It is believed that for the department to mandate one way or the other would introduce state medicine to the fullest extent.

**Advisory Committee** The attention of the local public welfare official is called to the value of securing the full co-operation of his county (district) medical society in the development of an approved local medical program. The State Department of Public Welfare agrees that there are advantages in the establishment of a medical advisory committee in each public welfare district and agrees to use and advocate the use of these committees and to assist in a general determination of their functions. These committees can advise and suggest and can recommend policies for supervision and administration but the responsibility for all acts and decisions must remain—and we believe should remain—in the hands of the local welfare official. State reimbursement on a local fee schedule is conditioned on the department's approval of this schedule as being reasonable for the particular community, rather than on the basis of a state-wide fee schedule. Considerable study is now being given to the question of medicines and drugs—a few localities having reached a fairly satisfactory solution of this problem.

lem,—and it can be expected that with local assistance much of the difficulty and criticism will eventually be eliminated. It is agreed that no ruling on a medical question should be made by a local welfare official in the absence of a definite recommendation by the medical advisory committee.

Attention is called to the value of an active professional advisory committee in providing the local public-welfare official with professional advice in the development and revision of the policies included in the approved local medical program, in the arbitration and discipline of professional problems and in the operation of survey boards to review and plan proper medical care for persons suffering from prolonged or disabling illnesses or presenting special or unusual medical needs. The medical advisory committee may be appointed from a list nominated for the purpose by the county (district) medical society. Where deemed advisable, related or integrated committees may be created in the same way to include representatives of other professions, institutions and laymen.

*Outpatient Departments and Clinics.* The hospital outpatient department should be used as a diagnostic center and treatment auxiliary, thereby frequently substituting this adequate service for the more costly hospital admission. Many welfare patients are admitted and kept in hospitals a week who could receive adequate studies by an outpatient diagnostic group. Savings in this field could be used to compensate more adequately the physician for better medical care.

With the establishment of the local medical plan, the department has no choice but to insist that existing clinics and other medical resources be used to the fullest, *reasonable* extent. The department does not, however, insist on the use of such resources where they fail to meet the purpose for which they were established. The department believes that where local clinics infringe on or exploit the local medical group, this is a matter for arbitration between local officials and professional groups, and not subject to state interference. Exploitation of the medical profession is unsound. It is entirely possible that, wherever local medical advisory committees really work and function, salaried practice and the overuse of clinics may be found to be increasingly less desirable medically, socially and economically. This is not to say that the solution of these problems will be merely a matter of simple evolution but rather to emphasize that their solution directly depends on the amount of thought and consideration given them.

*Co-ordination of Service Plans.* There are several methods of providing physicians' services. These methods, their costs and the results obtained vary with the locality, to a considerable extent dependent on the judgment and experience of the local welfare official and on the local conditions and needs with which he is confronted. However, nowhere in this state is there a formal, functioning mechanism that integrates and correlates all the services which are provided in a community at public expense. Current systems of expenditure for and distribution of tax-supported medical care may only *seem* to be economical. For example, if total costs were to be analyzed, it would be found that many cases are unnecessarily hospitalized thereby multiplying many times the cost of case management. Only by having the complete picture, especially regarding total individual costs, can the appropriate bodies, the welfare officials and the medical-care professions co-operate to the end that the medical needs of the individual and the community are met efficiently

as well as economically. It is hoped that machinery may be evolved which will supply this need.

Practically every plan designed to assist low-income groups or the indigent to obtain good medical care involves some reduction in the customary fees paid to physicians for similar services.

Rates must bear a reasonable relation between customary local expenditures for medical service and the ability of the public to pay.

The physician's overhead averages over 40 per cent. We realize that needs, costs and available revenue are interrelated items which affect the quality, adequacy and economy of tax-supported medical care.

Available revenue should be based on economics, and the physician should not be expected to carry the whole load. He pays his share of taxes to support welfare cases and then provides medical care to this group with monetary compensation that is, in some cases, ridiculously low.

ELMER S. BAGNALL, M.D.  
*Chairman*

#### *Subcommittee on Prepaid Medical-Care Costs Insurance*

The special committee having this matter in hand will offer the following six recommendations:

1. That permission be granted the Massachusetts Medical Service Corporation to co-ordinate its activities with the Blue Cross relative to (1) the presentation of joint contracts to subscribers and (2) administrative functioning and expense. This shall be done with each group retaining (1) its distinct independent corporate identity and (2) the right to issue separate contracts, the relation of the two corporations to be determined on a contract basis.

*Reasons:* Other medical groups have found this advantageous; industry will be interested in one contract and one payroll deduction, not two; we shall benefit by the prestige, sales approach and local experience of the Blue Cross; it is sound economically (independently, our overhead would be 22 to 24 per cent; conjointly, it may be 9 to 10 per cent).

2. That a special committee be appointed by the Executive Committee to select an executive director.

*Reasons:* The special committee has no time for this, and it would compromise our future usefulness to make a selection which might not be acceptable to a portion of the Society. Much ground must be explored: Should the director be lay or medical? Is the best man to be found locally or afield? Will the best man be found in organizations like the associated hospital or medical-service corporations of other states? To work over this ground requires a separate committee.

3. That authority be granted to the special committee to hire an actuary, provided that sufficient actuarial data are not made available to the committee through the Massachusetts Division of Insurance.

*Reasons:* Further progress requires accurate actuarial studies based on the experience of the Blue Cross in Massachusetts and that of medical-service schemes in other states. Such services should now be available to the special committee.

4. That income levels for eligibility for medical-service contracts (contrasted to medical-indemnity contracts) be set up at \$2000 for an individual and \$2500 for a family. At present, only medical-indemnity, and not medical-service, contracts shall be offered above these levels.

*Reasons* This is the median level established in Michigan. New Jersey established a \$1600 level but changed to \$2000, Buffalo started with a low level, but was required to raise it to \$1900 by the insurance commissioner, California set \$3000, Utica has no level. This level, on the basis of statistical studies includes the bulk of the low income wage earners of Massachusetts. A program with lower levels would exclude so many industrial wage earners that industry might not be interested and the program might fail. This simple basis of selection must be established or industry will not co-operate, they will not enter a complex contract calling for the establishment of varying income and family subdivision groups.

5 That contracts be prepared and presented on the following basis: (1) the quick preparation of a surgical contract for hospital surgical expense, (2) the preparation, as quickly as feasible, of a total hospital medical care contract to cover all medical fields incidental to hospital expense, (3) the careful slow preparation of a comprehensive medical-care contract covering total medical-care expense in the home, office and hospital, to be presented when the Massachusetts Medical Society so determines.

*Reasons* The final contract represents the ideal. To present it would require a year or two of study. The public may not be ready to accept the premiums of such a policy, as suggested by experience of other organizations. An early inadequate enrollment in this group would create a serious financial deficit. Industry and individuals and the statements of the Blue Cross indicate that hospital coverage for surgery or total hospital medical care is desired. Authorities state that this is the reasonable, sound approach. From this base we could educate the public to comprehensive medical care contracts, create a reserve, establish the corporation and start it functioning within a few months. There is need of urgent action which can be safely taken on the basis of all but the comprehensive medical-care contract.

6 That such sums as are indicated by the Commissioner of Insurance (presumably between \$10,000 and \$25,000) be loaned to the Massachusetts Medical Service Corporation by the Massachusetts Medical Society, and that other funds be raised by an enrollment fee from the participating physicians (to be returned to physicians enrolling within a given period of time, when, as and if the corporation is financially able to do so).

JAMES C. McCANN, M.D.  
*Chairman*

#### COMMITTEE ON MEDICAL EDUCATION

The committee has approved the following list of medical schools and colleges:

##### ARKANSAS

University of Arkansas School of Medicine, Little Rock

##### CALIFORNIA

University of California Medical School, Berkeley-San Francisco

College of Medical Evangelists, Loma Linda-Los Angeles

University of Southern California School of Medicine, Los Angeles

Stanford University School of Medicine, Stanford University-San Francisco

##### COLORADO

University of Colorado School of Medicine, Denver

##### CONNECTICUT

Yale University School of Medicine, New Haven

##### DISTRICT OF COLUMBIA

Georgetown University School of Medicine, Washington

George Washington University School of Medicine, Washington

Howard University College of Medicine, Washington

##### GEORGIA

Emory University School of Medicine, Atlanta

University of Georgia School of Medicine, Augusta

##### ILLINOIS

Loyola University School of Medicine, Chicago

Northwestern University Medical School, Chicago

Rush Medical College, University of Chicago

The School of Medicine of the Division of the Biological Sciences, University of Chicago

University of Illinois College of Medicine, Chicago

##### INDIANA

Indiana University School of Medicine, Bloomington-Indianapolis

##### IOWA

State University of Iowa College of Medicine, Iowa City

##### KANSAS

University of Kansas School of Medicine, Lawrence-Kansas City

##### KENTUCKY

University of Louisville School of Medicine, Louisville

##### LOUISIANA

Louisiana State University School of Medicine, New Orleans

Tulane University of Louisiana School of Medicine, New Orleans

##### MARYLAND

Johns Hopkins University School of Medicine, Baltimore

University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore

##### MASSACHUSETTS

Boston University School of Medicine, Boston

Harvard Medical School, Boston

Tufts College Medical School, Boston

##### MICHIGAN

University of Michigan Medical School, Ann Arbor

Wayne University College of Medicine, Detroit

##### MINNESOTA

## COMMITTEE ON MATERNAL WELFARE

CAUSES OF MATERNAL DEATH IN  
MASSACHUSETTS DURING 1940 (*continued*)

## HEMORRHAGE

The number of deaths due to hemorrhage (27) compares favorably with the number so allocated (36) in 1939. Table 1 presents an analysis of the cases.

*Post-partum hemorrhage.* In this series, post-partum hemorrhage was the primary cause of death in 10 cases. One case occurred in a patient with a blood pressure of 230 systolic, 120 diastolic, when she entered the hospital; however, an estimation of the record leads one to believe that the real cause of death was post-partum hemorrhage.

TABLE 1. *Deaths due to Hemorrhage.*

CAUSE	NO. OF DEATHS
Post-partum hemorrhage .....	10
Separated placenta .....	7
Placenta previa .....	5
Abortion .....	2
Inversion of the uterus .....	2
Varicosities .....	1

Two patients died of hemorrhage from two to four hours following delivery and after the attending physician had left the patient. It is unfortunate that transfusion was not used in any of these cases. One patient, on whom a cesarean section was performed, died two and a half hours after delivery. The physician was not in attendance at the time of the catastrophe, and no transfusion was given. One patient, a very unusual case, died of a profound hemorrhage two days after delivery. This, of course, could have been caused only by some type of retained placenta. In criticism, the general use of transfusion must be stimulated. Intravenous ergotrate and repeated transfusions should almost invariably ensure recovery in all cases of hemorrhage due to an atonic uterus. In none of these cases was hysterectomy attempted. This operation should always be considered in certain cases.

*Separated placenta.* Seven cases were classified as caused by separation of the placenta. Five were typical, completely separated placentas with the

characteristic tight uterus. In no case, it is interesting to note, was the Dublin method of cervical packing and the Spanish windlass employed. One case was treated as expertly as possible by a transfusion five times after hysterectomy had been performed and yet resulted fatally, which shows the inherent seriousness of this particular complication. *Accouchement forcé* was practiced in 2 cases. That this operation must never be employed—for whatever reason—has been brought out repeatedly in this column. The procedure has absolutely no place in obstetrics; it is never to be condoned.

*Placenta previa.* There were only 5 cases of placenta previa. It is interesting to note that the number of separated placentas as a cause of death is greater than the number attributed to placenta previa. Certainly, some type of separated placenta is a much commoner cause of bleeding than placenta previa. One case occurred in a patient who had had two previous cesarean sections, and in this pregnancy, a complete placenta previa and very free bleeding were present. At cesarean section, the placenta was found not only to be complete but to be a placenta accreta as well, and in spite of hysterectomy this patient succumbed. One patient with a complete placenta previa died undelivered; since she had been under observation in a hospital, there is little excuse for this fatality. It is evident from a review of these cases that transfusion does not play so important a part in the treatment of placenta previa as it should, and this must mean that some hospitals are not so adequately prepared for this procedure as they should be.

*Abortion.* There is little to be said of the abortions. Both these cases were probably criminally induced, and both patients died of massive hemorrhage. Had these patients been under good hospital care, death from this cause certainly would have been avoided.

*Inversion of the uterus.* It is very interesting that 2 cases of acute inversion of the uterus should occur in one year accompanied by massive uncontrollable bleeding that resulted in death. In neither case was the inversion suspected until after death. There is no excuse for the lack of diagnosis. Had the diagnosis been made, these patients probably would not have succumbed. Most acute inversions can readily be replaced under anesthesia, and those that cannot are readily replaced by laparotomy. It is difficult in any way to condone these deaths.

*Varicosities.* The case of the patient who died from bleeding from varicosities and vaginal tissue is most unusual. This patient was not transfused,

and so far as one can make out, oozing from the lacerated surfaces was uncontrollable.

\* \* \*

The decreased number of fatal hemorrhages is commendable. The lack of transfusion in many cases is hard to understand. If there are hospitals in Massachusetts today that are not equipped to deal with acute hemorrhage by transfusion, these hospitals are blameworthy. It is shocking to realize that 2 patients died of post-partum hemorrhage a few hours after delivery and after the medical attendants had left. Education should teach that *accouchement forcé* should never be employed in obstetrics, and emphasis on greater conservatism in the handling of separated placenta is necessary to reduce the mortality from this condition.

## POSTGRADUATE EXTENSION COURSES

The postgraduate extension courses are sponsored by the Massachusetts Medical Society in co operation with the Massachusetts Department of Public Health and the United States Public Health Service. The registration fee for the general course is \$5 00, with no fee for the course in venereal disease. All legally registered physicians of the Commonwealth are eligible to enroll. For further information, the chairman of the district committee on postgraduate instruction should be consulted.

The programs for the winter sessions are as follows:

BERKSHIRE DISTRICT PITTSFIELD	
Combined General and Venereal Disease Course*	
SUBJECT	DATE
Acute Abdominal Disease Among Infants and Children (Medical and Surgical Aspects)	
Syphilis of the Newborn. Early lesions of acquired syphilis and importance of intensive treatment, the rapid use of massive doses of arsenicals by continuous intravenous treatment; review of this modern therapy and its evaluation	March 12
Pediatrics Case Discussions and Clinics	
Cardiovascular Syphilis	March 19
Recent Advances in the Preoperative and Postoperative Care of Patients Requiring Major Surgery	
Differential Diagnosis and Treatment of Gonorrhea. Prevention and complications	March 26
Indications and Technic of Induction of Labor, with Case Histories	
Neurosyphilis as a Possible Factor in Diseases of the Nervous System	April 2
Fractures in General with Treatment	
Bone Lesions of Syphilis. Syphilitic skin lesions—differential diagnosis and treatment	April 9
Kidney Disease and Hypertension	
Lymphogranuloma Inguinale and Ducey's Bacillus Infection	April 16

\*One half of a session will be devoted to each subject

Subject to be announced

Pelvic Inflammatory Disease in the Female  
Due to Gonorrhea and Other Infections

April 23

Diagnosis and Treatment of Hemorrhage in  
Pregnancy, with Case Histories

Interpretation of Laboratory Data in the  
Diagnosis of Syphilis, Gonorrhea and  
Other Infectious Diseases

April 30

Meetings to be held at the Bishop Memorial Building,  
Thursdays, at 4:30 p.m.

Harry G. Mellen, M.D., *Chairman*  
150 North Street, Pittsfield

#### DEATHS

BRIGGS—J LYMONS BRIGGS, M D, of North Dighton, died January 3 He was in his seventy second year

Dr Briggs received his degree from Boston University School of Medicine in 1890 He was surgeon in chief at

the Massachusetts Memorial Hospitals from 1916 to 1932, and professor of surgery at Boston University School of Medicine from 1918 to 1932. He was a fellow of the American College of Surgeons and a member of the Massachusetts Medical Society, the Boston Surgical Society and the American Medical Association.

His widow survives him.

**PAINE**—MORTIMER H. PAINE, M.D., of South Hanson, died October 1. He was in his sixty-sixth year.

Dr. Paine received his degree from Tufts College Medical School in 1909. He was a former member of the Massachusetts Medical Society.

**SEARS**—HENRY F. SEARS, M.D., of Boston, died January 1. He was in his eighty-first year.

Dr. Sears received his degree from Harvard Medical School in 1887. He was assistant pathologist at the Boston City Hospital from 1888 to 1894, when he retired from active practice. He was a member of the Massachusetts Medical Society and the American Medical Association.

He is survived by two daughters and a son.

**STOWELL**—EDMUND C. STOWELL, M.D., of Marlboro, New Hampshire, died December 20. He was in his seventy-sixth year.

A native of New York, Dr. Stowell received his degree from Harvard Medical School in 1892. He was a member of the Massachusetts Medical Society and the New Hampshire Medical Society, and a fellow of the American Medical Association.

He is survived by his widow, three sons and a sister.

## WAR ACTIVITIES

### UNITED STATES ARMY

The following medical officers entered on active duty between December 28, 1941, and January 3, 1942:

Collins, Roy W., Lieut., of Colchester, Vermont: Fort Adams, Rhode Island.

Neff, Richard S., Lieut., of Boston, Massachusetts: Fort Devens, Massachusetts.

Borenstine, Joseph, Lieut., of Boston, Massachusetts: Fort Devens, Massachusetts.

Sutch, Gabriel, Lieut., of Howard, Rhode Island: Fort Devens, Massachusetts.

Scribner, Robert S., Lieut., of Haverhill, Massachusetts: Camp Edwards, Massachusetts.

Harris, Oliver J., Lieut., of Boston, Massachusetts: Westover Field, Massachusetts.

Criscuolo, Joseph A., Lieut., of New Haven, Connecticut: Fort H. G. Wright, Connecticut.

Windus, Charles E., Lieut., of New Haven, Connecticut: Army Air Base, Bangor, Maine.

Kriedberg, Marshall, Lieut., of Dorchester, Massachusetts: Army Air Base, Bangor, Maine.

Yavarow, Millin M., Lieut., of Everett, Massachusetts: Manchester Air Base, Manchester, New Hampshire.

Haselhuhn, Donald H., Lieut., of Springfield, Massachusetts: Army Air Base, Manchester, New Hampshire.

Lamb, Francis D., Lieut., of Warwick, Rhode Island: Windsor Locks, Connecticut.

Duennevier, Harold W., Lieut., of Hartford, Connecticut: Windsor Locks, Connecticut.

## CORRESPONDENCE

### PREMARITAL MEDICAL EXAMINATION

*To the Editor:* Since the passage of the Massachusetts premarital health examination law, certain problems have confronted both physicians and official agencies who have needed clarification. Among these problems is the nature of the examination required by the law. Because of the increasingly confused situation, the Department of Public Health decided to submit this question to the Attorney General's Office for legal interpretation.

We enclose a copy of the Department's letter to the Attorney General requesting interpretation of certain provisions of the premarital health examination law and copy of the Attorney General's reply. We believe the publication of this correspondence in the *Journal* will help physicians to understand more adequately the requirements of the law.

We also enclose a copy of the law which you may wish to reprint in the *Journal*.

PAUL J. JAKMAUH, M.D.  
*Commissioner of Public Health*

State House  
Boston

\* \* \*

November 21, 1941

The Honorable Robert T. Bushnell  
Attorney General  
State House  
Boston

*Dear Sir:*

There seems to be considerable confusion among many physicians concerning the nature of the examination required by Chapter 601, as amended by Chapter 697, of Acts of 1941, "An Act Relative to the Filing of Notice of Intention of Marriage."

The act requires a health examination before city and town clerks and registrars may accept filing of notices of intention of marriage. That part of the law which describes the examination required reads as follows: "Such physician, in making such examination, discover evidence of any infectious disease declared by the state department of public health to be dangerous to the public health. . . ." The examination is further defined in the next sentence, which reads, "Such examination shall include a standard serological test for syphilis. . . ."

Since the list of infectious diseases declared by the Department of Public Health to be dangerous to the public health includes some forty diseases, many of which require elaborate laboratory examinations for their detection, complete examination for each of these diseases would be impractical except in those cases in which symptoms or signs definitely indicate its presence.

Our own impression is that the law specifically requires only a laboratory test for syphilis and that any other laboratory or diagnostic test should be made only where the examination suggests an infectious disease for the detection of which an additional diagnostic test is necessary.

We wonder if you would be willing to interpret those sections of the act which bear upon the examination required, for possible release to the *New England Journal of Medicine*.

Very truly yours,

PAUL J. JAKMAUH, M.D.  
*Commissioner of Public Health*

December 1, 1941

Paul J Jakmaul, MD  
Commissioner of Public Health  
State House  
Boston

Dear Sir

You have written to ask my opinion as to the interpretation of those provisions of G L., c 207, s 20B—enacted as St 1941, c 601, s 1, and amended by St 1941, c 697—which deal with an examination to be made by a physician of the parties to an intended marriage. The pertinent provisions of the statute are as follows:

Except as hereinafter provided, such notice of intention of marriage shall not be accepted by the clerk or registrar until he has received from each party to the intended marriage a certificate signed by a qualified physician registered and practicing in the commonwealth or a commissioned medical officer on active service in the armed forces of the United States who has examined such party as hereinafter provided. If such physician, in making such examination, discovers evidence of any infectious disease declared by the state department of public health to be dangerous to the public health, he shall inform both parties of the nature of such infectious disease and of the possibilities of transmitting the same to his or her marital partner or to their children. Such examination shall include a standard serological test for syphilis and said test shall be made by a laboratory of said department or by a laboratory approved by it for such test.

The examination of such physician and the laboratory test shall be made not more than thirty days before the filing of the notice of intention of marriage.

You state that there is considerable confusion among physicians concerning the nature of the examination required by this statute, and that this arises from their uncertainty as to whether or not the parties must be examined for all infectious diseases declared by the Department of Public Health to be dangerous to the public health.

At the time St 1941, c 601, was enacted some forty infectious diseases, including syphilis, had been declared by your department, pursuant to G L., c 111, s 6, to be dangerous to the public health. You have furnished me with a list of these, which is still in force, and you inform me that for the detection of many of them an elaborate laboratory examination is necessary.

In my opinion syphilis is the only one of these infectious diseases the presence or absence of which must be determined in the manner prescribed, as a part of the examination required by G L., c 207, s 20B, as amended. I am led to this conclusion primarily by the terms of the statute, which provide that the physician shall inform the parties regarding any of these diseases of which he discovers evidence in making his examination, but which require, in the case of syphilis, that the examination shall include a specific test to be made in a specified laboratory.

Moreover, since only one laboratory test must be made seems manifest from the provision that the examination by such physician and the laboratory test should be made not more than thirty days before the filing of the notice of intention. Yet, as you inform me, many of the diseases referred to cannot be detected without various laboratory tests. This fact furnishes added support to the

conclusion that the physician is not required to determine the presence of any of the infectious diseases other than syphilis, as distinguished from merely discovering evidence of such diseases.

If the Legislature had intended the examination to determine the presence or absence of every disease in the category named, it undoubtedly would have so provided, and the expression of the requirement of a laboratory test as to one disease indicates that its omission as to the other diseases was intentional. (Cf *Boston & Albany R R Co v Commonwealth*, 296 Mass 426, 434.)

On the other hand, I believe that the physician's examination should be of such nature as to disclose any evidence of the infectious diseases referred to, which a physician could reasonably be expected to discover without a laboratory test. My opinion in this regard is based upon the manifest purpose of the statute, which is to protect the public health by measures which are reasonably calculated to deter the transmission, incident upon marriage, of the designated infectious diseases. The method adopted is a compulsory examination by a physician, including one laboratory test. The only object of the examination is to enable the physician to enlighten the parties to the intended marriage regarding the nature and transmissibility of any infectious disease, in the specified group, of which he discovers evidence. Plainly, in order to carry out the purpose of the statute, the physician's examination should be directed toward the discovery of such evidence.

Very truly yours,

ROBERT T BUSHNELL  
Attorney General

State House  
Boston

\* \* \*

#### CHAPTER 601 AS AMENDED BY CHAPTER 697, OF THE ACTS OF 1941

An Act further regulating the filing of notices of intention of marriage, and the delivery of certificates of such intention and the return of unused certificates.

**Section 1** Chapter two hundred and seven of the General Laws is hereby amended by inserting after section twenty A, inserted by section three of chapter two hundred and sixty-nine of the acts of nineteen hundred and thirty-nine, the following new section—  
Section 20B Except as hereinafter provided, such notice of intention of marriage shall not be accepted by the clerk or registrar until he has received from each party to the intended marriage a certificate signed by a qualified physician registered and practicing in the commonwealth or a commissioned medical officer on active service in the armed forces of the United States who has examined such party as hereinafter provided. If such physician, in making such examination, discovers evidence of any infectious disease declared by the state department of public health to be dangerous to the public health, he shall inform both parties of the nature of such infectious disease and of the possibilities of transmitting the same to his or her marital partner or to their children. Such examination shall include a standard serological test for syphilis and said test shall be made by a laboratory of said department or by a laboratory approved by it for such test.

Such certificate by a physician registered and practicing in the commonwealth shall read as follows—

I (name and address of physician), a registered physician of (city or town) in the commonwealth of Massachusetts declare that on (month, day, year) I examined (name and address of party) in accordance with section twenty B of chapter two hundred and seven of the General Laws. This certificate is made under the penalties of perjury.

Such certificate by a commissioned medical officer on active service in the armed forces of the United States shall read as follows:—I (name and address of physician) a (rank or title) serving in the (name of unit) of the United States on oath declare that on (month, day, year) I examined (name and home address of party) in accordance with section twenty B of chapter two hundred and seven of the General Laws of the commonwealth of Massachusetts.

Blank forms of certificates required under this section shall be furnished to city and town clerks by the department of public health.

The examination by such physician and the laboratory test shall be made not more than thirty days before the filing of the notice of intention of marriage. Whoever fails to comply with this section shall be punished by a fine of not less than ten nor more than one hundred dollars. In extraordinary or emergency cases where the death of either party is imminent or where the female is near the termination of her pregnancy, upon the authoritative request of a minister, clergyman, priest, rabbi or attending physician, the clerk or registrar may accept such notice of intention without having received the physician's certificate hereinbefore referred to.

**Section 2.** Section twenty-eight of said chapter two hundred and seven, as appearing in the Tercentenary Edition, is hereby amended by striking out, in the third and in the eleventh lines, the words "six months" and inserting in place thereof, in each instance, the words:—sixty days,—so as to read as follows:—**Section 28.** On or after the fifth day from the filing of notice of intention of marriage, except as otherwise provided but not in any event later than sixty days after such filing, the clerk or registrar shall deliver to the parties a certificate signed by him, specifying the date when notice was filed with him and all facts relative to the marriage which are required by law to be ascertained and recorded, except those relative to the person by whom the marriage is to be solemnized. Such certificate shall be delivered to the minister or magistrate before whom the marriage is to be contracted, before he proceeds to solemnize the same. If such certificate is not sooner used, it shall be returned to the office issuing it within sixty days after the date when notice of intention of marriage was filed.

**Section 3.** Section fifty-seven of said chapter two hundred and seven, as so appearing, is hereby amended by striking out, in the second and in the fourth and fifth lines, the words "six months" and inserting in place thereof, in each instance, the words:— sixty days,— so as to read as follows:—**Section 57.** Whoever performs a ceremony of marriage upon a certificate more than sixty days after the filing of the notice of intention of marriage as set forth in such certificate, and whoever having taken out such certificate and not having used it fails to return it, within sixty days after such filing, to the office issuing the same, shall be punished by a fine of not more than ten dollars.

## DISTORTED PUBLICITY

*To the Editor:* A great deal of publicity has been given to my paper in *Science* (94:2437, 1941), entitled "Clinical Achromotrichia," a preliminary report. Again, newspaper and magazine publicity is given on the paper given by me, in collaboration with Dr. Stefan Ansbacher, at a meeting of the Society of Experimental Biology and Medicine on November 12, 1941, at the New York Hospital, New York City. Photographs were shown of Dr. Ansbacher and myself in a review of medical progress by Waldemar B. Kaempffert in *Look* magazine (December 31, 1941). Many facts have been distorted and many preliminary findings that were mentioned were amplified, resulting in misrepresentation and unfair comment.

It is my purpose in this letter to ask the medical profession to realize that newspaper and magazine reports are written for the public, many times resulting in distortion and misquotes as to the facts. Further investigation is being carried on and will be published in a recognized medical journal as soon as enough laboratory and clinical results are compiled. The work that has been done and is being done is sincere, scientific and ethical. I am attempting in every way possible to take care of all requests by the medical profession for material and information concerning treatment.

It is best to state that para-aminobenzoic acid is becoming more and more difficult to obtain because of priority legislation, its mother substance being toluene, which is also necessary in the production of trinitrotoluene.

BENJAMIN F. SIEVE, M.D.

371 Commonwealth Avenue  
Boston

## BOOK REVIEWS

*Field Service Notes for Regimental Officers.* By E. M. Colwell, C.B.E., D.S.O., T.D., F.R.C.S., A.D.M.S. 16<sup>1</sup>/<sub>2</sub> cloth, 148 pp., with 29 illustrations. London: J. and A. Churchill, Limited, 1940.

This is a practical, pocket-size book with helpful directions to junior line officers of the new British Army. Officers of the Medical Corps also will find much that is worth while. Covering the duties of officers in field service and in charge of troops in billets and camps, it fills a valuable place, and should greatly aid the younger line officers in caring for the welfare, health and comfort of British soldiers under their charge.

*Dietetics for the Clinician.* By the late Milton A. Bridges, M.D. Fourth edition, thoroughly revised. 8°, cloth, 960 pp., with 83 tables. Philadelphia, Lea and Febiger, 1941. \$10.00.

This is a particularly useful book for the physician of today, for he, much more than the practitioner of the past, is expected to understand dietetics as applied to the care of the sick as well as he does pharmacology and materia medica. He must be prepared to discuss diet with his patients as he does drugs, and he must be able to write his order for a diet to the dietitian as intelligently as he writes his prescription to the pharmacist.

This volume, the fourth edition of a work previously developed and edited by the late Dr. Bridges, had been planned by him but had to be completed by his devoted collaborators, all clinicians and teachers in medicine. The result is a book fully informative and readily applicable to all dietary problems in daily practice.

## *SALMONELLA SUIPESTIFER* INFECTION IN BOSTON\*

### A Report of Eleven Cases, with Autopsy Findings in a Case of Bacterial Endocarditis Due to this Organism, and a Study of the Agglutination Reactions in this Infection

N. ERNEST GOULDER, M.D.,† MARGARET F. KINGSLAND, A.B.,‡ AND CHARLES A. JANEWAY, M.D.§

BOSTON

ALTHOUGH *Salmonella suispestifer*¶ infection has been infrequently reported in New England, it has occurred often enough in our experience to warrant emphasis on some of its peculiarities. The organism now known as *S. suispestifer* was isolated in 1885 by Salmon and Smith from swine with hog cholera. This disease of swine is now known to be caused by a filterable virus, but it is frequently complicated by an acute intestinal inflammation due to *S. suispestifer*. In 1902, Longcope<sup>1</sup> reported 2 cases of infection in man caused by an organism that was later identified by TenBroeck as belonging to the *suispestifer* group.

During World War I, *suispestifer* organisms were identified as the causative agents of a number of mild epidemics of acute gastroenteritis. In 1919, MacAdam<sup>2</sup> reported an epidemic in Mesopotamia, and Hirschfeld reported one in Serbia. Since then, many reports of similar epidemics have been published, and by 1937 Harvey<sup>3</sup> had compiled a total of 1425 cases occurring in epidemics. From these studies, it became evident that the epidemic form of infection was characterized by a brief incubation period, followed by the abrupt onset of fever, headache, abdominal pain, vomiting and diarrhea, fairly rapid recovery and a very low mortality. This organism must therefore be considered a possible etiologic agent in an epidemic of so-called "food poisonings."

Once the epidemic form of the infection became known, sporadic cases began to be reported, characterized by diverse clinical findings and by a very high mortality rate in adults. In his 1937 review, Harvey<sup>3</sup> listed approximately 70 cases of this type. Bacteremia has been noted in about 60 per cent of these sporadic cases. Clinically, the patients are often without localizing signs of infection and present a typhoidal picture characterized by an acute onset, marked fever lasting from two to ten days, headache, anorexia, vomiting, coryza, dry cough and abdominal pain. In a few cases, shaking chills, joint pains or diarrhea may occur, and children may show drowsiness, meningismus and even convulsions. As in typhoid fever, the white-cell count tends to be depressed unless the infection localizes. Although the organism is readily cultured from the blood, it is rarely observed in the stools.

When localization of the infection occurs, the lungs appear to be a site of predilection, for bronchopneumonia develops in about 30 per cent of the patients. The clinical course is characterized by high fever, daily variations in temperature as great as 2°F, and a gradual subsidence. Rarely is the organism found in the sputum; Bullowa,<sup>4</sup> in 1928, reported one such case, which was associated with lobar pneumonia. Pleural effusion, a rare finding, was reported by Boller<sup>5</sup> in 1930, by Cohen, Fink and Gray<sup>6</sup> in 1936, and by Harvey<sup>3</sup> in 1937.

Other frequent sites of localization are the bones and joints. Pyarthrosis and osteomyelitis appear in 20 per cent of the cases several days to a few weeks after the onset of the infection. The involved joint is warm, swollen and tender and, on aspiration, yields greenish fluid from which the organism may be cultured. Osteomyelitis of ad

¶Although the official name for *Salmonella suispestifer* is *S. cholerae suis*, the former name is so much more familiar that we have continued to use it in the text. For the nomenclature and classification of the commoner members of the *Salmonella* group, see Table 3.

joining bones frequently develops, and with the progression of the disease, the usual x-ray findings appear.

Purulent meningitis characterized by coma, convulsions, cervical rigidity and a positive Kernig sign was reported by Materna and Januschke<sup>3</sup> in 1925, by Kuttner and Zepp<sup>6</sup> in 1932, by Boycott and McNee<sup>7</sup> in 1936, and by Ravitch and Washington<sup>8</sup> in 1937. A case of pericarditis was described in 1936 by Cohen, Fink and Gray.<sup>5</sup> Clifton and Werner,<sup>9</sup> in 1938, presented a patient with bilateral subdural abscesses. Although the urinary tract is usually spared in these infections, mild cystitis has occasionally occurred. Other urinary-tract complications are rare, but in 1918, Neukirch<sup>10</sup> reported a case of pyelonephritis, and in 1925, Ssokoloff<sup>3</sup> described a case of perinephric abscess.

From this survey of the clinical features of *suipestifer* infections, it is apparent that although the disease tends to follow a typhoidal course, it may localize in any one of a number of sites, of which the lungs, bones and joints are the commonest. Furthermore, the infection appears oftenest under conditions that reduce the resistance of the patient. *Suipestifer* epidemics therefore tend to develop in populations already weakened by starvation and exposure, and sporadic cases often appear in people suffering from some chronic disease, such as diabetes, malaria, tuberculosis or neoplasm.\* This fact may account for the typical high mortality rate.

#### SUIPESTIFER BACTERIAL ENDOCARDITIS

The occurrence of bacterial endocarditis in *suipestifer* infections has been mentioned only in recent years. In 1931, TenBroeck, Li and Yü<sup>12</sup> reported a case of acute vegetative mitral endocarditis in a patient with blood cultures positive for *Bacterium paratyphosum* C, which belongs to the *suipestifer* group. Gouley and Israel,<sup>13</sup> in 1934, studied a case of *suipestifer* bacteremia in a four-year-old boy who developed a rough mitral murmur and later a double aortic murmur during his illness. Inasmuch as the child recovered, the clinical diagnosis of *suipestifer* endocarditis could not be proved. In 1939, Forster<sup>14</sup> reported 2 cases of fatal bacterial endocarditis that were proved to be due to *S. suipestifer* by bacteriologic studies at necropsy. One patient was a forty-seven-year-old Negro with tertiary syphilis who developed fever, leukocytosis and an apical systolic murmur of in-

creasing intensity. Three blood cultures were positive for *S. suipestifer* (American type). At post-mortem examination, the heart showed syphilitic aortitis, with extension to the myocardium, and acute ulcerative mural endocarditis of the right atrium and left ventricle. The second was a thirty-one-year-old laborer with rheumatic heart disease, who developed a spiking temperature, chills, leukocytosis and a variable diastolic murmur; seven blood cultures were positive for *S. suipestifer* (American type). At post-mortem examination, the heart showed chronic rheumatic pancarditis, with focal epicarditis, fibrosis of the aortic, mitral and tricuspid valves, and acute ulcerative mitral endocarditis. In both cases, the bacillus was recovered from the endocardial vegetations; the hearts had already been damaged by chronic disease, and the clinical course in each was stormy, with fever, leukocytosis and rapid progression. Later in 1939, Read<sup>15</sup> reported a third case of *S. suipestifer* endocarditis proved at autopsy. This occurred in a forty-nine-year-old woman with a rapidly enlarging abdominal tumor, considered to be an ovarian cyst. On paracentesis, the fluid removed from the cyst was found to contain *S. suipestifer* (European type). Septicemia due to this organism developed after operation, and systolic and diastolic murmurs appeared at the aortic area. At post-mortem examination, the heart showed acute bacterial aortic valvulitis, but there was no evidence of antecedent injury. We report below a fourth case of *S. suipestifer* endocarditis, which was studied in 1940 on the medical wards of the Peter Bent Brigham Hospital.

#### CASE REPORT

CASE 1. S. W. (P. B. H. 57907), a 58-year-old Russian-born housewife, entered the hospital on September 6, 1940, because of chills and fever of 3 days' duration. She had had an attack of "rheumatism" at the age of 26, and a heart murmur had been noted at the age of 32. For many years, she had experienced gaseous indigestion and heartburn after eating fried foods. For 4 years, she had noticed increasing shortness of breath on exertion. Three days before entry, she had a severe chill, followed by headache and fever, and accompanied by vomiting and knifelike epigastric pain. These symptoms persisted, and hospitalization was advised. One month before this episode, she had spent 2 weeks in the country, where she drank raw milk and well water, but no one else in her party had become ill.

Physical examination revealed an elderly obese woman, drowsy, mildly confused and dehydrated, who had a temperature of 103°F., a pulse of 95, respirations of 30 and a blood pressure of 120/70. The conjunctivas were injected, the pupils and fundi were normal, and the tongue was heavily coated. The heart was moderately enlarged to the left, with a prominent systolic thrill in the aortic area, and also at the apex. A loud, rough systolic murmur

\*One of the most striking examples of the course of *suipestifer* infection in a patient with neoplasm was reported by Gray<sup>14</sup> in 1936. The patient, a 36-year-old Negro with a *suipestifer* bacteremia, ran a prolonged febrile course due to abscesses in myomas of the uterus. These presumably acted as foci for reinfection. After a supravaginal hysterectomy, the patient recovered.

was heard in both areas. The pulse at the wrist was of the plateau type. Although there was slight epigastric tenderness, neither the spleen nor the liver was palpable.

The blood Hinton and Wassermann reactions were negative. The urine showed small amounts of protein at times, an occasional red blood cell and 3 to 4 white blood cells per high power field, and occasional hyaline and granular casts in the centrifuged sediment. The red-cell count fell progressively from 4,550,000 to 2,700,000, and the hemoglobin from 93 per cent to 60 per cent (Sihli). The white-cell count decreased from 21,000 to 13,000, and 90 per cent of the white blood cells in stained blood smears were neutrophils. The sedimentation rate was

x-ray films showed marked cardiac enlargement, with diffuse clouding of the lungs, suggestive of pulmonary edema. At that time, sulfapyridine therapy was started, and a total of 20 gm was given in 3 days. Because of the development of oliguria, hematuria and slight pitting edema, the drug was discontinued on the 3rd day. The temperature rose again, the signs of consolidation at the right base progressed, and abdominal distention, dyspnea and cyanosis appeared. Sulfapyridine therapy was again started on the 19th hospital day, and a total of 20.5 gm was given in the course of 3 days. Although the temperature dropped somewhat, coarse rales appeared over both lung bases, generalized edema was noted, and the

FIGURE 1 Clinical Course in Case 1

44 mm per hour (Wintrobe). Blood chemical findings included chlorides of 90 milliequivalents per liter, a distaste of 4 mg and a nonprotein nitrogen of 54 mg per 100 cc, a total protein of 5.9 gm, an albumin of 2.2 gm and a globulin of 3.7 gm per 100 cc. The icteric index was 10. The electrocardiogram showed left axis deviation and premature auricular beats. An x-ray film of the gall bladder region showed a shadow compatible with a distended gall bladder. X-ray study of the kidney and bladder regions was negative.

Five blood cultures made at various times during the hospital course were positive for *S. suis* (European type). Three urine cultures were similarly positive, and of four stool cultures, one made a week after entry yielded the same organism. On entry, the blood serum agglutinated both the H and O antigens of *S. suis* to a serum dilution of 1:40. A week later, the titer had risen to 1:1280 for both antigens.

During the first 6 days of the hospital course, the temperature fluctuated, with daily rises to a level between 102 and 104.5°F, often with chills (Fig 1). On the 7th day, the administration of sulfathiazole was started, and although 32 gm was given for 5 days, the temperature still remained high, with daily variations. On the 14th day, the temperature reached a peak of 105°F. Signs of consolidation appeared over the right lower lobe, and

venous pressure was found to be 220 mm of water. Despite oxygen and Digalen therapy, the patient died on the 22nd hospital day.

The discharge diagnoses included *S. suis* septicemia, *S. suis* endocarditis (?), rheumatic heart disease, inactive, with aortic stenosis, and bronchopneumonia.

**Autopsy.** A postmortem examination, limited to the neck, chest and abdomen, was performed on September 27, 1940, 4 hours after death. The pathological diagnoses included septicemia due to *S. suis*, subacute bacterial endocarditis of the mitral valve caused by *S. suis*, acute bronchopneumonia, pulmonary infarction (recent), focal hemorrhage and necrosis of liver, embolic nephritis, acute splenitis, rheumatic heart disease, myocardial fibrosis, stenosis and insufficiency of mitral and aortic valves, cardiac hypertrophy and dilatation, generalized arteriosclerosis, generalized congestion, pulmonary edema, hydropericardium, hydrothorax, dependent edema, pulmonary emphysema and atelectasis, and pulmonary infarction (old).

The heart weighed 560 gm. Its valve measurements were tricuspid, 10 cm, pulmonary, 7.5 cm, mitral, 5 cm, and aortic, 5 cm. The myocardium of the left ventricle measured 2.5 cm in thickness, and that of the right ventricle 0.8 cm. The left ventricle was contracted,

and the left atrium, right ventricle and right atrium were dilated. The tricuspid and pulmonary valves were not remarkable. The mitral valve admitted only the little

FIGURE 2.

finger, and its cusps were markedly thickened. A large, soft, reddish vegetation measuring 1.5 by 1 by 0.5 cm. was attached to this portion of the posterior cusp

lar surface of the anterior cusp. The aortic valve had rigid, thickened, roughened leaflets obstructing the lumen of the valve. Marked calcification was present in the aortic ring and extended upward into the leaflets. No gross vegetations were noted. The endocardium of the left atrium was somewhat thickened. The papillary muscles were hypertrophic, and the myocardium was pale red and markedly friable. The openings of the coronary arteries were somewhat narrowed by the marked arteriosclerotic processes in the sinuses of Valsalva. The coronary arteries were moderately tortuous, and their intima displayed numerous yellowish plaques.

On microscopic examination, the myocardium revealed a few small areas of fibrosis and scattered foci of cellular infiltration composed of lymphocytes, plasma cells, monocytes and polymorphonuclear leukocytes. A number of small recent hemorrhages were present without appreciable cellular response. The mural endocardium in one section was markedly thickened, consisting of hyaline connective tissue, with some infiltration of lymphocytes and plasma cells. Beneath the endocardium was a fairly wide zone of granulation tissue infiltrated with lymphocytes and polymorphonuclear leukocytes. The mitral valve revealed fibrosis, newly formed blood vessels and infiltration with polymorphonuclear leukocytes, lymphocytes, plasma cells and monocytes. Its atrial surface was covered by a large thrombus of fibrin enclosing cellular debris, red and white blood cells, and myriads of small gram-negative bacilli in large clusters (Fig. 4). The tissue immediately underlying the thrombus showed marked leukocytic infiltration and some fibroblastic proliferation.

Cultures taken during the post-mortem examination from the heart's blood, spleen and mitral vegetation were positive for *S. suispestifer* (European type).

#### CLINICAL FEATURES IN SUIPESTIFER ENDOCARDITIS

Except for the presence of bacterial endocarditis, the post-mortem findings in our case were com-

FIGURE 3.

(Figs. 2 and 3). Tiny, granular, friable vegetations were present along the entire line of closure of the mitral valve. The chordae tendineae were thickened and shortened. Plaques of calcified material were present on the ventricu-

patible with those usually found in cases of *suipestifer* bacteremia. The pathology is that of a severe infection and frequently includes bronchopneu-

monia, acute splenitis, focal necrosis of the liver and petechial hemorrhages. Pyarthrosis and osteomyelitis are not infrequent, and meningitis, pericarditis, cystitis, pyelonephritis and abscesses

FIGURE 4.

in various parts of the body are found occasionally. To the list of unusual findings, bacterial endocarditis must be added.

The salient features of the 4 proved cases of

no case was the spleen palpable. Fever was high and was associated with chills in all, and leukocytosis, an unusual finding in uncomplicated suispestifer bacteremia, occurred in all the cases. Changing murmurs were noted in 3 patients. Positive blood cultures were readily obtained, and in the only case in which it was mentioned, the agglutination titer was high. Chemotherapy with the sulfonamide drugs was attempted in 3 of the 4 cases, with no evidence that it had an appreciable effect on the course of the disease.

Thus, endocarditis due to *S. suispestifer* may occur and should be suspected whenever changing murmurs, leukocytosis and embolic phenomena are associated with a bacteremia due to this organism.

#### OTHER CASES OF SUIPESTIFER INFECTION IN BOSTON

The appearance of this case of suispestifer endocarditis prompted a review of other cases of suispestifer infection seen in clinics cooperating with the Peter Bent Brigham Hospital.

#### *Suispestifer* Infection in Children\*

Six cases are reported from the Children's Hospital of Boston. These were all due to the European type of *S. suispestifer*. The fact that they are all fairly recent is probably due to more ac-

TABLE 1. Comparison of Four Cases of *Suispestifer* Endocarditis.

AUTHOR	AGE OF PATIENT	SEX	WHITE-CELL COUNT	RED CELL COUNT	TYPE OF ORGANISM	AGGLUTININ TITER	SITE OF LESION	NO OF POSITIVE BLOOD CULTURES	COMMENT
FORSTER <sup>14</sup>	47	M	11 4-33 4	5 0	American	—	Right atrium, left ventricle	3	Patient, a Negro, had had syphilitic aortic insufficiency. Onset of acute and ulcerative endocarditis was insidious. Heart block and increasing systolic murmurs were noted. Hospital course lasted for 6 days.
	31	M	16 0-26 0	5 5-3 2	American	—	Mitral valve	7	Patient had had rheumatic fibrosis of mitral, aortic and tricuspid valves. Onset of acute, ulcerative endocarditis was insidious. Auricular fibrillation and inconstant diastolic murmurs were noted. Hospital course lasted for 21 days. Petechiae and infarcts were noted in spleen, kidney and lungs at autopsy.
READ <sup>15</sup>	49	F	11 7-20 0	5 5-3 9	European	—	Aortic valve	1	Onset of acute endocarditis was postoperative. Aortic systolic and diastolic murmurs were noted. Hospital course lasted for 66 days. Cerebral thrombosis was present.
Gould, Kingsland and Janeway	59	F	13 7-21 0	4 5-2 7	European	H 1 1280 O 1 1280	Mitral valve	5	Patient had had rheumatic mitral and aortic stenosis and insufficiency. Onset of subacute endocarditis was sudden. Premature auricular beats and loud systolic murmurs were noted. Hospital course lasted for 22 days. Infarcts in kidney and lungs were found at autopsy.

bacterial endocarditis due to *S. suispestifer* are summarized in Table 1. In 3 cases, the endocarditis was superimposed on a valve already damaged, twice by rheumatic infection, and once by syphilis. Embolic phenomena were noted in 3 cases—in the skin, spleen, lungs, kidneys and brain. Clubbing of the fingers was absent. In

curate bacteriologic classification than to an increased incidence of the disease.

CASE 2. J. V. (C. H. 178921), a 6-year-old boy, was admitted to the hospital on February 5, 1934, because of a 2-day episode of fever, vomiting and cough productive of

\*We are indebted to the late Dr. Kenneth Blackfan, former physician in chief of the Children's Hospital for permission to report Cases 2, 3, 4, 5, 6, 7 and 11 from the Children's and Infants' hospitals.

blood-streaked sputum. Physical examination revealed an acutely ill boy with numerous ecchymoses on the legs, inflamed tonsillar pillars, pharyngitis, signs of consolidation in the lower portion of the right upper lobe of the lungs and a palpable spleen. The white-cell count was 17,400, and the red-cell count was 4,550,000. A blood culture taken on the day of entry was positive for *S. suispestifer* (European type). The temperature rose to 106°F. on the 2nd day, and then gradually declined until it became normal on the 7th hospital day. During the first week, 2 stool cultures were positive for *Shigella paradysenteriae* (Sonne). The patient was therefore kept in the hospital for 23 days, to obtain a sufficient number of negative stool cultures. One month after discharge, the agglutination titer was 1:320 for the suispestifer H antigen, and 1:640 for the O antigen.

CASE 3. D. G. (C. H. 189434), a 4-month-old boy, was admitted to the hospital on February 15, 1935, because of fever and diarrhea of 2 days' duration. Physical examination revealed a febrile, restless infant with pharyngitis and an inflamed left tonsil. The white-cell count was 15,000, and the red-cell count was 5,050,000. Several stool cultures were positive for *S. suispestifer* (European type), but blood cultures were negative. During the first few days, the patient had numerous loose greenish stools and ran a fever varying from 101 to 102.8°F. The temperature became normal on the 11th hospital day. On the 15th day, the spleen became palpable, but he was in such good condition that he was discharged 2 days later.

CASE 4. T. W. (C. H. 190092), a 9-year-old boy, entered the hospital on March 18, 1935, because of abdominal pain, fever and delirium of 5 days' duration. Physical examination revealed pharyngitis, a palpable spleen and slurred speech. The white-cell count was 4400, and the

CASE 6. B. E. (C. H. 207904), a 2-year-old girl, entered the hospital on June 11, 1938, because of fever, marked sweating, vomiting and diarrhea of 24 hours' duration. Physical examination revealed a drowsy, apathetic, febrile child. The white-cell count was 6000, and the red-cell count was 4,800,000. A blood culture was positive for *S. suispestifer* (European type). The patient ran a high fever and leukopenia for the first 2 days, but the diarrhea promptly subsided. On the 3rd day, the temperature became normal, and the patient was no longer apathetic. She was discharged on the 10th day after three properly spaced stool cultures were reported negative.

CASE 7. R. D. (C. H. 209725), a 2-year-old boy, was admitted to the hospital on June 10, 1939, because of fever and convulsions of 24 hours' duration. Physical examination revealed pharyngitis, rapid breathing and signs of consolidation in the right axilla. The white-cell count was 9600, and the red-cell count was 3,500,000. Two blood cultures were positive for *S. suispestifer* (European type). A lumbar puncture was negative. On the 1st day, the temperature reached a peak of 105°F. It gradually declined until it became normal at the end of the 2nd week. On the 5th hospital day, the liver and spleen became palpable. The patient was discharged on the 21st day.

These cases of suispestifer infection in children were all sporadic. The clinical picture was that of an acute infectious disease, which ran a febrile course of three to fifteen days. The age of the patients varied from four months to nine years, and with one exception all were males. Two cases had acute gastroenteritis with diarrhea. Pharyngitis

TABLE 2. *Suispestifer* Infection in Children.

red-cell count was 5,900,000. A lumbar puncture revealed normal spinal fluid. Blood cultures were positive for *S. suispestifer* (European type). The temperature ran from 99 to 100°F. for the 1st week. It then became normal, the patient's irritability subsided, and the spleen was no longer palpable. Before discharge on the 15th day, the agglutination titer was 1:320 for both H and O antigens.

CASE 5. A. L. (C. H. 183420), a 6-year-old boy who had been treated in the Out-Patient Department for a meatal stricture, was admitted to the hospital on September 30, 1935, because of fever, anorexia and difficulty in passing urine. These symptoms began a week before entry and had gradually increased in severity. Physical examination was negative except for fever and a reddened glans with 2 meatal orifices. The white-cell count was 5400, and the red-cell count was 4,530,000. A blood culture was positive for *S. suispestifer* (European type). Both fever and urinary difficulty subsided by the 3rd day, and on the 7th day the patient was discharged.

was found in 4 patients, a palpable spleen in 3, and signs of pneumonia in 2. Only 2 patients had a definite leukocytosis. Of these, one had pneumonia and the other had acute gastroenteritis. Five had positive blood cultures; the one exception was a four-month-old child who had a positive stool culture. These data are summarized in Table 2.

*Suispestifer* Infection Complicating Parturition

Two cases of *S. suispestifer* infection occurred recently in women at the Boston Lying-in Hospital. In each case, the infection was due to the European type of the organism, and its source was unknown. Both newborn infants acquired the infection. One developed coryza, with a positive stool culture, and recovered; the other devel-

oped positive blood, spinal fluid and stool cultures, and died

CASE 8 H T (B L H 29220), a 21 year-old primipara, was admitted to the hospital on March 28, 1940, because of sharp pain in the right flank, radiating down the right thigh to the calf, of 24 hours duration. Prior to admission, she had treated herself with local application of hot water bottles to the right flank and had suffered

more small blood transfusions, and the temperature fell to normal on the 10th hospital day, she made a rapid convalescence. On April 4, she began to complain of severe pain over the right sacroiliac region. On April 20, x-ray films showed slightly diminished radiance and roughening of the articular surface at the inferior border of the right sacroiliac joint. This pain disappeared after 2 or 3 weeks. Agglutination tests for *S. suispestifer* were positive to serum dilutions of 1:80 and 1:320 on April 1,

FIGURE 5 Clinical Course in Case 8

second-degree burns. On admission, the temperature was 100.6°F, the pulse 86, the respirations 20, and the blood pressure 104/58. The patient seemed acutely ill, but tenderness in the right costovertebral angle was the only positive physical finding.

The urine contained 3 or 4 white blood cells per high power field in the centrifuged sediment of a catheterized specimen. The hemoglobin was 40 per cent (Sahli), the red cell count was 2,340,000, and the white cell count 11,100. An x-ray film of the kidney region showed no evidence of stone. There was a total blood protein of 5.51 gm, an albumin of 2.98 gm, a globulin of 2.08 gm, and a nonprotein nitrogen of 34 mg per 100 cc. Culture of the urine gave a growth of *Staphylococcus aureus* and hemolytic streptococcus.

During the next 2 days, the temperature rose to 104°F, and the patient experienced five chills during this period (Fig. 5). Blood cultures taken on March 28 and March 30 were positive for *S. suispestifer* (European type). Because of anemia, the patient was given a blood transfusion. On March 30, she went into labor and delivered a baby girl without particular difficulty. Because of persistent fever and signs in the left chest, an x-ray film was taken and interpreted as showing consolidation of the left lower lobe due either to pneumonia or more probably to pulmonary edema resulting from acute cardiac decompensation. Sulfapyridine was administered, and 18 gm was given during the next 4 days without any demonstrable effect on the disease. Several attempts to isolate *S. suispestifer*, streptococci and pneumococci from the sputum were unsuccessful. The patient was given four

of 1:320 and 1:640 on April 10 and of 1:640 and 1:640 on April 27 for the H and O antigens, respectively.

In a follow-up visit on August 15, the patient reported that she had been in good health since her discharge on April 29. The sacroiliac arthritis had not troubled her, and an x-ray film taken at that time showed definite narrowing of the joint and reaction in the bones on either side of the joint, apparently the end result of an inflammatory process. On April 16, 1941, O agglutination of *S. suispestifer* was negative, and H agglutination positive to a serum dilution of 1:160.

CASE 9 Baby T (B L H 29220) was born on March 30, 1940, to the patient in Case 8 by a normal delivery. During the 1st week of life, the baby appeared ill, with poor color, cry and activity and finally developed coryza and a fever reaching 100°F. A stool culture on the 20th hospital day gave a light growth of *S. suispestifer* (European type). Blood taken at the time of discharge on April 29 gave a positive agglutination for *S. suispestifer*, but all blood cultures were negative. A year later, the baby was seen and found to have normal weight and development.

CASE 10 T C (B L H 29171), a 23-year-old para III, who had lost her second child during an attack of eclampsia, was admitted to the hospital on April 13, 1940, 24 hours after delivery on the district service. During pregnancy, the patient was quite anemic. Delivery was by breech extraction with forceps. Delivery of the after-coming head. During this process, the patient lost 300 cc of blood. On the following day, the temperature rose

progressively to 103°F., with a pulse of 150, and hospitalization was therefore advised.

On admission, the patient appeared extremely pale and acutely ill. The temperature was 105°F., the pulse 136, and the respirations 30. Physical examination was otherwise negative.

The urine contained many gram-negative motile rods and 4 or 5 white blood cells per high-power field in the sediment. Examination of the blood showed a red-cell count of 1,770,000 with a hemoglobin of 30 per cent (Sahli), and a white-cell count of 7900. The stained blood smear showed marked variation in the size and shape of the red blood cells, and two nucleated red blood cells were noted. The total blood protein was 5.37 gm. per 100 cc. Cultures of the urine were positive for colon bacilli on three occasions. Two blood cultures were negative, but two out of eight stool cultures showed *S. suispestifer*. Agglutination tests with typhoid bacilli, paratyphoid A and B. bacilli, and *Brucella abortus* were negative, but on April 26 were positive for the H and O antigens of *S. suispestifer* (European type) to a serum dilution of 1:80. Agglutination of a strain of *Escherichia coli* from the stool was very slight.

The patient was given daily transfusions of 500 cc. of citrated blood for the first 6 days, and 1 cc. of concentrated liver extract daily from April 19 to April 23. The temperature, pulse and respirations fell gradually to normal by April 22. At discharge on May 7, the hemoglobin had risen to 84 per cent, and the white-cell count was 7500. Throughout the hospital course, the white-cell count fluctuated between 7900 and 2400.

The patient was seen again on April 16, 1941, when she stated that she had been in excellent health since a subtotal thyroidectomy in January, 1941, performed to relieve hyperthyroidism, which had developed soon after the termination of her pregnancy. At this time, no agglutinins for either the H or O antigen of *S. suispestifer* were detected in her blood.

CASE 11. Baby C. (B. L. H. 23915), a male infant, was born at term on April 12, 1940, to the patient in Case 10 by breech extraction with forceps delivery of the head. The birth weight was 5 pounds, 6 ounces. At 24 hours, the patient was admitted to the Boston Lying-in Hospital with his mother, who was suffering from acute pyelonephritis due to *Esch. coli* and who was later found to harbor *S. suispestifer* in her intestinal tract. For 9 days, the baby appeared well, except for the persistence of jaundice and an episode on the 9th day when the temperature fell to 95°F. On April 22, the temperature rose to 100.8°F., and the patient appeared feeble, apathetic and hypoactive. The extremities were cold and cyanotic, the mucous membranes were pale, and the abdomen was distended. On April 23, the red-cell count was 4,400,000 with a hemoglobin of 75 per cent, and the white-cell count was 14,400. A blood culture was found to be positive for *S. suispestifer* (European type). Because of this infection, the patient was transferred on April 26 to the Infants' Hospital.

On admission, the baby was found to be poorly nourished and poorly developed, apathetic, jaundiced and slightly hyperpneic. The mucous membranes were pale, the abdomen was distended, and the spleen, kidneys and liver were palpable.

The urine sediment contained a few white blood cells and many granular casts per high-power field. The red-cell count was 3,300,000 with a hemoglobin of 80 per cent, and the white-cell count was 21,200. The blood Hinton reaction was negative, the icteric index 90, and the non-

protein nitrogen 58 mg. per 100 cc. Lumbar puncture showed yellowish spinal fluid with a +++ test for globulin, normal sugar, a red-cell count varying from 450 to 5400, and a white-cell count varying from 12 to 92. The last included polymorphonuclear and mononuclear cells. Cultures of the spinal fluid, blood and stools were all positive for *S. suispestifer* (European type), but no agglutinins were found in the blood.

During the 7 days that the infant was at the Infants' Hospital, the temperature was constantly subnormal. Because of recurrent episodes of cessation of respiration, intracranial damage was suspected, and lumbar punctures were performed. The baby was given intravenous glucose and small transfusions, 10 gr. of sulfanilamide for the first 2 days and 63 gr. of sulfathiazole for the next 4 days. Despite all therapy, the patient died May 5, on the 21st day of life. Permission for an autopsy was not granted. The discharge diagnoses were *S. suispestifer* bacteremia and birth injury of the brain, with subarachnoid hemorrhage.

### Summary of Cases

Two other cases of adult infections in Boston were reported in 1936 by Walker, Weiss and Nye.<sup>10</sup> Unlike the cases presented in this paper, these infections were due to the American type of *S. suispestifer*. In one case, a left subdiaphragmatic abscess developed in a twenty-three-year-old salesman who previously had experienced a severe illness characterized by fever, chills and diarrhea. The organism was cultured from the abscess when it was drained at operation. In the second case, a forty-year-old Negress had a cholecystectomy for chronic cholecystitis, and the organism was cultured from the gall bladder at operation.

To these cases, we now may add 11 more cases of sporadic infection due to the European type of *S. suispestifer*—6 cases in children, 2 in newborn infants, 2 in parturient women and 1 in an elderly woman. In this group, 2 deaths occurred—one in a newborn infant, who developed both bacteremia and meningitis, and the other in the elderly woman, who developed bacterial endocarditis. Since the ages ranged from the newborn period to fifty-eight years, there appears to be universal susceptibility to infection of this type. All the patients had high fever, ranging in duration from eight to thirty-eight days. Eight patients had positive blood cultures; the other 3 had positive stool cultures. The patient with bacterial endocarditis had positive stool and urine cultures, in addition to positive blood cultures. The composite clinical picture included chills and fever, coryza and pharyngitis, pneumonia, splenomegaly, abdominal pain, vomiting, diarrhea, arthritis, meningitis and bacterial endocarditis. In uncomplicated bacteremia, the white-cell count tended to remain low, but once localization of the infection occurred, leukocytosis usually developed.

## LABORATORY DIAGNOSIS OF SUIPESTIFER INFECTIONS

The diagnosis of infection due to *S. suipestifer* is made by isolation of the organisms, which can most frequently be done by blood culture and less frequently by stool or urine culture. Once isolated, these organisms are readily identified as members of the paratyphoid group by their morphology (gram negative bacilli), motility, fermentation of dextrose, with the production of gas, and inability to ferment lactose.

Further identification depends on the use of special tests, both fermentative and serologic. *S. suipestifer* is distinguished from all the other *Salmonella* organisms by its inability to ferment arab

of agglutination tests in this large group of morphologically similar organisms have been enormously enhanced by the work of White and of Kauffmann,<sup>17</sup> whose painstaking antigenic analyses carried out with carefully absorbed serums have resulted in the so called "Kauffmann-White scheme of classification."

Weil and Felix<sup>18</sup> first introduced the terms "H" and "O" as applied to motile and nonmotile variants of a culture, H standing for *Hauch* (flagella), O for *ohne Hauch* (without flagella). H agglutinins are antibodies to the antigens of the flagella of the bacteria, and their union with the flagella results in the formation of loose clumps

TABLE 3 Classification of the Commoner *Salmonella* Organisms\*

\*There are many other organisms in Groups B, C and D a total of 68 being listed in the last edition of Bergey's *Determinative Bacteriology*.

†The typhoid bacillus (*Escherichia typhosa*) although not strictly a *Salmonella* organism is antigenically a member of Group D with an antigen formula 9 12 d. It is always in the specific phase.

inose. Its inability to ferment inositol and trehalose may be used as confirmatory evidence. It is distinguished in this manner from *S. hirschfeldii* (paratyphoid C bacillus, also known as the Eastern type of *S. suipestifer*) which ferments arabinose, usually trehalose, but not inositol. The American and European types, known as *S. suipestifer* and *S. suipestifer var. kunzeendorf* respectively, are separated on the basis of hydrogen sulfide production, which can best be tested by the use of Kligler's iron agar. The European type produces hydrogen sulfide, which gives black colonies on Kligler's agar, whereas the American type does not.

Although these biochemical reactions justly deserve an important place in the classification of the gram negative bacilli, most laboratories make use of agglutination tests with stock antisera to confirm the tentative identification made by sugar fermentations. The accuracy and specificity

and prompt immobilization of the motile bacteria. Thus, H agglutination becomes readily visible within two hours at 55°C as large, coarse flocules, or microscopically is visible almost instantly as an immobilization of the bacteria with the formation of loosely tangled groups of organisms. On the other hand, the O or somatic agglutinins are directed to the antigens of the cell bodies. If the organisms are motile, or if the flagella are preserved as in a formalinized suspension, O agglutination does not occur, because H agglutination occurs first. However, if the flagella are removed by chemical treatment, or by the production of a nonmotile variant, O agglutination can be demonstrated. Since the bacterial bodies are sensitized, tight packing of the bacteria takes place as agglutination proceeds. Consequently, the clumps formed are small, and it takes six to twelve hours at 55°C for macroscopic agglutination to occur. H suspensions are either live mo-

tile cultures or formalinized suspensions. O suspensions are prepared from a nonmotile variant or by treating a culture of a motile organism with 50 per cent alcohol for twenty-four hours, or with a temperature of 100°C. for 15 minutes, either of which procedures destroys the H antigens. H agglutination tests are read after two hours at 55°C. and refrigeration overnight; O agglutination tests are read after six hours at 55°C. and refrigeration overnight.

The Kauffmann-White classification<sup>19, 20</sup> divides the *Salmonella* organisms into eight different groups on the basis of their O or somatic antigens, which are conventionally represented with Roman numerals. The different species within the groups are separated on the basis of their H or flagellar antigens, for which small letters are used, or, in some cases, on the basis of minor O antigens. Unfortunately, many of these organisms can exist in two phases. In the specific phase, an organism possesses flagellar antigens peculiar to itself, but in the group phase the flagellar antigens are common to many other members of the *Salmonella* group. These group H antigens are represented by Arabic numerals. Table 3 gives the antigenic formulas for the commoner members of the *Salmonella* group, arranged according to Kauffmann's scheme, with the various names used for the different species.

It will be noted that *S. suispestifer* (American type) can exist in both group and specific phases, whereas *S. suispestifer* var. *kunzensdorf* (European type) can exist only in the group phase. Thus, when the former is in the group phase, it cannot be distinguished from the latter by agglutination, and the test for hydrogen sulfide production must be used.

When all this is known, it becomes apparent that the use of the agglutination reaction is beset with pitfalls unless one knows what phase the antigens are in and what phase the organism was in when injections were made to produce the diagnostic serum. If only H agglutination is used, mistakes may be frequently made. For example, the antigenic formula for *S. schottmuelleri* (paratyphoid B bacillus) is IV, XII, V : b : 1, 2, and that for *S. typhi murium* is IV, XII, V : i : 1, 2, 3. These two organisms are among the most frequent to be isolated from *Salmonella* infections in this area. If an organism is isolated that seems to belong to the *Salmonella* group, it would probably be tested first in serum made against *S. schottmuelleri*. If the serum were made with organisms in the group phase, it would contain antibodies to the group flagellar antigens 1 and 2. If the unknown organism happened to be *S. suispestifer* var. *kun-*

*zensdorf*, which is always in the group phase, it would agglutinate to a marked extent, because its flagellar antigens are 1, 3, 4 and 5, the first of which it shares with *S. schottmuelleri*. This confusion can be straightened out by fermentation tests with arabinose and trehalose, both of which are fermented by *S. schottmuelleri* and not by *S. suispestifer*. Furthermore, if the unknown culture is heated to boiling for half an hour to destroy the H antigens, it can then be retested as an O suspension. Under these conditions, it will agglutinate only in a serum made against a member of Group C, which contains somatic antigens VI and VII. This is a very useful procedure, which we have had to use in completing the identification of the organisms isolated from some of the cases reported in this paper, since they gave H agglutination in both our stock *suispestifer* and paratyphoid B antisera.\*

It is therefore quite obvious that the final identification of many *Salmonella* strains is beyond the scope of the ordinary hospital laboratory. On the other hand, the *Salmonella* Center† in New York City is equipped for antigenic analysis, and strains may be sent there for identification. Although this procedure seems like a rather academic matter, it is of great epidemiologic interest to identify as many strains as possible, so that data on the distribution and mode of spread of these organisms may be obtained.

Next to a blood culture, the agglutination test is most useful in making a diagnosis of this type of infection, and should be used in cases of obscure fever. In Harvey's<sup>3</sup> series of cases, 88 per cent gave positive agglutination reactions by the fourth week of the disease. It is essential to get serum from a patient early in the disease, so that it may serve as a control for later tests, which may show positive reactions.

To ascertain the value of the agglutination test in the diagnosis of *S. suispestifer* infection in the Boston area, we have studied a considerable number of serums. We have used both H and O antigens, the former prepared by formalinizing an eighteen-hour culture of the European type of *S. suispestifer* (group phase), and the latter by a twenty-four-hour treatment of the culture with 50 per cent alcohol. From what has already been said, a positive O agglutination would be expected following any infection caused by a member of Group C, and a positive H agglutination would occur after infection with any organism of the

\*Subsequent antigenic analysis of the paratyphoid B strain from which our stock antiserum was made has shown that it has organisms in both the group and the specific phases, which accounts for the lack of specificity of our paratyphoid B antiserum and antigen.

†The *Salmonella* Center, Beth Israel Hospital, New York City, corroborated our bacteriologic diagnosis in Cases 1, 8 and 9.

Salmonella group that happened to be in the group phase and to contain any of the flagellar antigens 1, 3, 4 and 5. In typhoid infection, it is believed that O agglutination is of more significance than H agglutination, since the latter may be increased as a result of prophylactic inoculation, whereas the titer of the former rises less with immunization but may go very high with infection.

We studied a number of normal serums to determine whether agglutinins for *S. supestifer* were present. A similar study was made with serums taken from patients six weeks after immunization with typhoid paratyphoid B vaccine. Since none of these serums showed any significant degree

sistence of agglutinins following infection with this organism. We were able to obtain serums from 6 patients who had had their infections from one to six years previously.

The data on these cases and on all the agglutination tests are summarized in Tables 4 and 5.

The Widal test, as ordinarily done, consists in testing an unknown serum against suspensions of typhoid and paratyphoid A and B bacilli. It is much more sensible to adapt it to the needs of the locality. In the Boston area, the commonest Salmonella infections are due to *S. schottmuelleri* (*Bact. paratyphosum B*), *S. typhi murium* and *S. supestifer var. kunzendorf*, so that suspensions of these organisms should be used in the Widal test. The inclusion of a suspension of *S. supestifer var. kunzendorf* has the added advantage of being in the group phase and, thus, of being able to detect antibodies to the group phase of almost all members of the Salmonella group. The other suspensions should be in the specific phase. We include a single O suspension, usually prepared from typhoid bacilli, in our Widal test, since there is some evidence that O antibodies are less specific in man than in rabbits. Moreover, O antibodies may occasionally develop in typhoid fever without H antibodies.

#### SUMMARY AND CONCLUSIONS

From a survey of the literature, it is apparent that *Salmonella supestifer* infection occurs in epidemic

TABLE 4 Results of Agglutination Tests with Serums from Normal Subjects and Those Immunized with Typhoid Paratyphoid B Vaccine

of agglutination with either the H or O antigen, it must be assumed that a positive agglutination test for *S. supestifer* has considerable significance in this locality. However, since our patients with supestifer infections developed equally high titers of H agglutinins for *S. supestifer* suspensions and for our stock suspension of *S. schottmuelleri* (para-

typhoid B bacillus),\* H agglutination is not specific. But when titers for both H and O agglutinins are found to be elevated, we consider it diagnostic of infection with *S. supestifer* or a related organism in Group C.

Another important question concerns the per-

\*See first footnote on page 136

form as acute food poisoning, with low mortality, and in endemic form at any age, with a considerable mortality, because it often complicates some debilitating disease. These latter cases are characterized by fever, frequently leukopenia, bacteremia and a tendency for the infection to localize in the bones, joints or lungs.

Eleven cases of sporadic infection occurring in the vicinity of Boston during the past six years are reported.

The clinical course and post-mortem findings in a fatal case of bacterial endocarditis due to *S. supestifer* in a fifty-eight-year-old woman with rheumatic valvular disease are described.

The bacteriologic diagnosis of this infection is discussed. A positive blood culture most frequently reveals the diagnosis, occasionally a positive stool or urine culture. *S. supestifer* is identified as a paratyphoid bacillus that does not ferment arabinose.

The significance of the agglutination reaction in this infection is discussed. Agglutinins for *S. supestifer* were not found in normal serums, nor in the serums of patients immunized with typhoid-paratyphoid B vaccine. High agglutination titers were found in the serums of most patients with supestifer infection, and these persisted for periods varying from a few months to six years after infection in a small group of cases.

The importance of using standard antigens and properly prepared antiserums in the identification of the various *Salmonella* types is pointed out.

## THE ACTION OF FURMETHIDE (FURFURYL-TRIMETHYL-AMMONIUM IODIDE) ON THE BLADDER IN PATIENTS WITH URINARY RETENTION FOLLOWING SURGERY ON THE RECTUM\*

### Preliminary Report

JOSEPH H. LIPTON, M.D.,† SAMUEL B. BEASER, M.D.,‡ AND MARK D. ALTSCHULE, M.D.§

BOSTON

A NUMBER of parasymphomimetic drugs, such as Mecholyl and Doryl, are known to cause contraction of the bladder, but untoward side effects limit their clinical use. A new parasymphomimetic drug, Furmethide (furfuryl-trimethyl-ammonium iodide), has been found to have a strong action on the bladder and relatively little effect on the cardiovascular or gastrointestinal system, so that distressing side reactions are not common following its use in the treatment of the atonic bladder. The action of Furmethide

is being studied at present in a wide variety of bladder atonies, including those associated with diabetes, lesions of the spinal cord, postoperative states and trauma to the bladder. Since a complete evaluation of the effectiveness of the drug will require many months, it is considered desirable to call attention to its usefulness by describing its action in one of the syndromes studied, that is, urinary retention following operations on the rectum.

### MATERIAL AND METHODS

All patients, excluding those with prostatic obstruction, subjected to abdominoperineal operations for carcinoma of the rectum during the period of this study were observed. They were placed on constant catheter drainage for ten to fourteen days after operation, or until they were

\*From the Medical Research Laboratories and the Medical, Urologic and Surgical services, Beth Israel Hospital, and the Department of Medicine, Harvard Medical School

This investigation was aided by a grant from Smith, Kline and French Laboratories, Philadelphia

§Associate in medicine, Harvard Medical School, associate visiting physician, Beth Israel Hospital

ambulatory Intermittent catheterization was employed following removal of the tube. No treatment was given if the volume of residual urine was small. If, however, it was greater than 300 cc, or if the patient could not void spontaneously, treatment with Furmethide was begun. This report is based on the results in 3 consecutive cases. Twelve patients with normal uninfected bladders were used for control studies.

A continuous flow recording cystometer of the type described by Prien<sup>1</sup> was used, previous studies by one of us (J H L) had demonstrated its sensitivity and accuracy. The patient was placed in the recumbent position and, after he had voided, was catheterized, control cystometric measurements were made of vesical pressure during filling, first

TABLE 1 *Average Effect of 5 Mg Furmethide on Cystometric Measurements in 12 Normal Subjects*

OBSERVATION	BEFORE DRUG	AFTER DRUG
Vesical pressure	11-17 cm. water	7-57 cm. water
First desire to void	150 cc	40 cc
Slight discomfort or fullness	400 cc	50 cc
Severe discomfort or fullness	410 cc	55 cc
Maximal voluntary pressure	0 cm. water	80 cm. water
Vesical capacity	410 cc	75 cc

desire to void, slight discomfort or fullness, severe discomfort or fullness, maximal voluntary pressure and vesical capacity. Furmethide was then given

residual urine, cystometric studies showed normal vesical pressure during filling, first desire to void at 400 cc and a vesical capacity of 425 cc. After the administration of 5 mg of Furmethide subcutaneously, a marked increase in vesical pressure during filling occurred (Fig 2), with first desire to void at 40 cc and a vesical capacity of only 50 cc. A second determination yielded similar results. Sweating, lacrimation and salivation occurred. The next day, 4 mg was given subcutaneously, 300 cc of urine was voided spontaneously within 10 minutes, and the residual urine volume was only 75 cc. Voiding of small amounts continued during the day. On June 10, the administration of 30 mg subcutaneously resulted in spontaneous voiding, with a residual urine volume of 20 cc. On the next day, the drug was not given and the residual urine increased to 150 cc. On June 12, the drug was given orally, in doses of 10 mg, twice during the day, the patient voided well and the residual urine volume was only 20 cc. The drug was discontinued on June 14, and at the time of discharge 5 days later, the residual urine volume was still only 50 cc.

CASE 2 A 67-year-old man was subjected to a one stage abdominoperineal resection of an adenocarcinoma of the rectum on March 4, 1941. Constant catheter drainage was continued until March 17, after which intermittent catheterization repeatedly yielded 450 cc of residual urine. Cystometric studies 5 days later showed normal tension, first desire to void at 300 cc, and a vesical capacity of 400 cc (Fig 3). The administration of Doryl subcutaneously from March 18 to 22 did not appreciably affect bladder function, the residual urine volume ranging between 150 and 390 cc. The administration of 5 mg of Furmethide subcutaneously caused a marked increase in vesical pressure during filling, with desire to void at 90 cc and a vesical capacity of 140 cc (Fig 3). On March 23, 3 mg

FIGURE 1 *Effect of Furmethide on the Normal Bladder*  
The asterisks indicate the first desire to void

subcutaneously in doses of 3 to 5 mg. Within five minutes, mild salivation, sweating, a feeling of warmth and a desire to void occurred. A second series of cystometric measurements was begun at this time. The effects of the injection of Furmethide on the bladders of the 12 control subjects are summarized in Table 1 and Figure 1.

#### CASE REPORTS

CASE 1 A 64-year-old man was subjected to a one stage abdominoperineal resection of an adenocarcinoma of the rectum on May 24, 1941. The tumor was found to be fixed to the base of the bladder, which was accordingly mobilized extensively and its serosa stripped away. Constant urinary drainage was begun after operation and continued until June 8, after which the patient voided only in small amounts and was found to have 400 cc of

of the drug was given subcutaneously after which the patient voided 350 cc and was found to have only 100 cc of residual urine. On the following 2 days, no drug was given, and 475 cc of residual urine was found repeatedly. Beginning on March 26, the drug was given orally in doses of 10 mg three times a day. Spontaneous voiding was maintained, and the volume of residual urine decreased to 20 cc on March 30. At the time of discharge on April 3, the residual urine was still less than 30 cc.

CASE 3 A 45-year-old man was subjected to a one stage abdominoperineal resection for adenocarcinoma of the rectum on May 23, 1941. Constant catheter drainage was employed until June 6, after which the volume of residual urine ranged between 400 and 900 cc. Cystometric studies on June 13 showed a neurogenic bladder curve, with first desire to void at 800 cc and a vesical capacity of 850 cc. After the administration of 5 mg of Furmethide subcutaneously, there was an increase in vesical pressure during filling with first desire to void at 100 cc and a

vesical capacity of 150 cc. (Fig. 4). On a regime of 5 mg of the drug subcutaneously, twice daily, the volume of residual urine decreased to 150 cc. On June 18, the drug

urine to 40 cc.; withdrawal of the drug resulted in an increase to 250 cc. on September 18, with first desire to void at 325 cc. and a vesical capacity of 500 cc. Since that

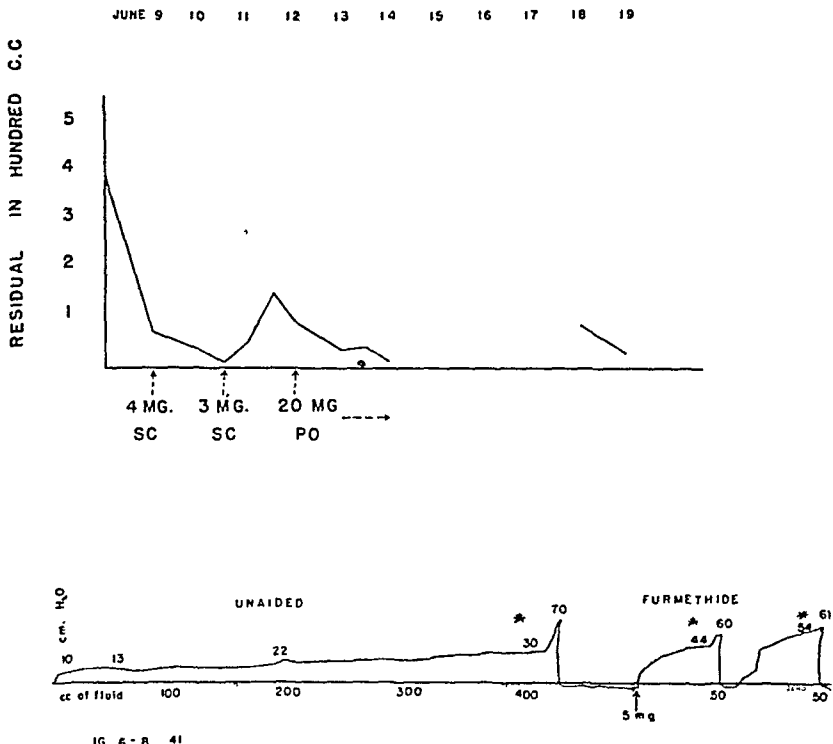

FIGURE 2. Findings in Case 1.

was started orally, in doses of 25 mg. twice daily, and the residual urine volume rapidly decreased to 40 cc. The patient was discharged, with orders to continue that

time, the patient has been taking 10 mg. of Furmethide by mouth twice daily. He empties his bladder almost completely, the stream is full, and he has no urinary symp

dosage; on July 9, the volume of residual urine was 50 cc., and cystometric studies yielded essentially normal results, with first desire to void at 210 cc. and a vesical capacity of 280 cc. The drug was discontinued, and on July 23 the residual urine volume was 250 cc. Resumption of oral Furmethide therapy reduced the volume of residual

toms. He experiences only mild sweating and a feeling of warmth after taking the drug.

DISCUSSION

The importance of urologic complications following major operations on the rectum has been

stressed by Ewert<sup>2</sup> and by Seaman and Binnig.<sup>3</sup> Ewert found 219 cases of urologic disturbance among 750 cases with operations on the colon, 75 per cent of them in patients after rectal surgery; some of the patients required tidal drainage for periods of one to three months. Seaman and

fore considered. The effective manner in which the administration of Furmethide has been found to control bladder dysfunction following major operations on the rectum is clearly exemplified by the findings in the cases described.

When Furmethide is given in doses of 3 mg.

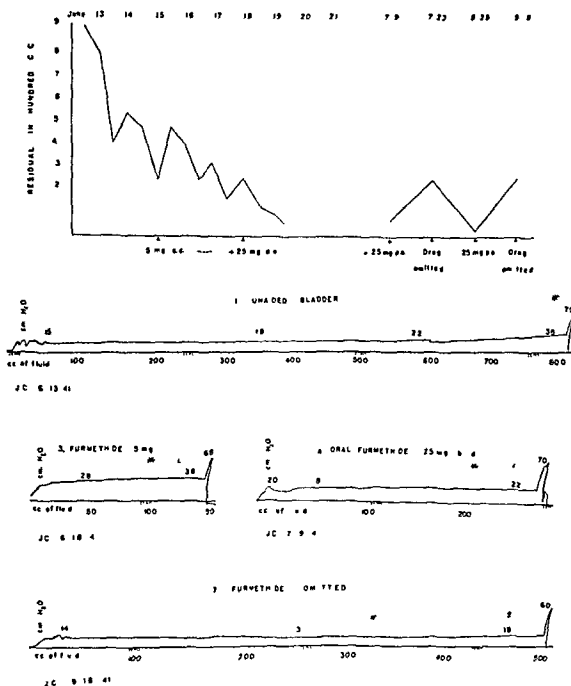

FIGURE 4 Findings in Case 3

Binnig<sup>3</sup> also reported the frequent need for tidal drainage following resection of the rectum and mentioned attempts to control the symptoms by means of the injection of Mecholyl and ergotamine tartrate. A similarly high incidence of urinary complications after abdominoperineal resection has been observed at the Beth Israel Hospital. It was believed that bladder dysfunction after resection of the rectum was probably due to detrusor atony resulting from damage of the parasympathetic nerve supply of the bladder, and that the administration of parasympathomimetic drugs might therefore control the symptoms. The employment of Mecholyl and of Doryl having proved generally unsatisfactory, the clinical uses of Furmethide, previously shown by other authors<sup>4-6</sup> to have somewhat similar pharmacologic effects, was there-

subcutaneously or 10 mg. by mouth, the side reactions consist only in slight sweating and a feeling of warmth. With somewhat larger doses, these symptoms are more marked, and salivation is pronounced. Still larger doses, that is, 10 mg. subcutaneously or 30 mg. by mouth, cause severer discomfort and may also give rise to nausea and vomiting. In all cases studied thus far, however, it has been possible to find a dose of the drug that is effective in its action on the bladder and does not cause significant discomfort because of the side effects.

The chemical similarity of Furmethide to Mecholyl and Doryl is based on the fact that all contain a trimethyl ammonium halide group (Fig. 5). Furmethide differs from the other two pharmacologically in that its action on the heart and lungs

is weaker than that of Mecholyl, its action on the gastrointestinal tract is weaker than that of Doryl, and its action on the bladder is consid-

FIGURE 5. Structural Formulas of Mecholyl, Doryl and Furmethide.

erably stronger than both. The advantages of these properties for the control of atony of the bladder are clear.

## SUMMARY AND CONCLUSIONS

The action of Furmethide (furfuryl-trimethylammonium iodide) on the normal bladder and on the bladder that has become atonic after major operations on the rectum is described. Its effect is to increase tone, restoring it in atony to or toward normal. The drug has been used effectively in the control of bladder dysfunction in 3 cases after abdominoperineal resection of carcinoma of the rectum. Although discomfort due to side reactions may be appreciable after administration of large doses of Furmethide, in clinical usage it has been possible to find a dose that is effective in its action on the bladder and does not cause significant discomfort because of the side effects.

## PRIMARY ADENOCARCINOMA IN A MECKEL'S DIVERTICULUM

HOLLIS L. ALBRIGHT, M.D.,\* AND JOHN S. SPRAGUE, M.D.†

BOSTON

INCREASING attention is being directed to Meckel's diverticulum, as judged by the reports in the literature of collected rather than single cases. The diverticulum has been estimated to be present in 2 per cent of all adults (Nygaard and Walters,<sup>1</sup> and Skinner and Walters<sup>2</sup>). It is usually observed as an incidental finding either at operation or at post-mortem examination. Symptoms do not usually arise until pathologic changes have taken place in the diverticulum. The complications are frequent, varied and almost always severe, and are of prime clinical importance; they may lead in some cases to an acute surgical emergency, and in others to a belatedly recognized cause of death. Attention is directed here to neoplastic disease of the diverticulum, particularly carcinoma.

Normally, the yolk stalk (omphalomesenteric

duct), which connects the alimentary canal with the yolk sac, becomes closed during the fifth week of fetal life. Failure of this duct to become completely obliterated may lead to any one of four anomalies. If the duct remains entirely open, an intestinal fistula results, with discharge of ileal contents through the umbilicus; this differs from a patent urachus because of the discharge of feces rather than urine. Secondly, if the duct remains open throughout its distal portion, an umbilical fistula results, with active secretion from its glandular lining. Thirdly, if the duct becomes obliterated at both ends but fails to close in the middle, a retention cyst or true enterocystoma forms, requiring surgical removal. Fourthly, if only the distal end closes and the ileal end remains open, a true Meckel's diverticulum results.

There are several distinguishing characteristics of a Meckel's diverticulum. It is usually located from 25 to 100 cm. from the cecum, almost always on the antimesenteric border. According to Reiser,<sup>3</sup> the wall usually lacks the circular mus-

\*Instructor in surgery, Boston University School of Medicine; visiting surgeon, Massachusetts Memorial Hospitals.

†Assistant in surgery, Boston University School of Medicine; second assistant visiting surgeon, Massachusetts Memorial Hospitals.

culature. When all the layers of normal intestine are present, the diverticulum may actively discharge its contents. In the case reported here, the diverticulum was 1 cm. away from the mesenteric border. The neck may vary widely in size, from the usual broad sessile type to the very narrow, as in our patient. A very narrow opening into the ileum may lead to impaction and decomposition of the diverticular contents. This may explain why preoperative x-ray studies with barium fail to disclose the diverticulum.

Histologically, the diverticulum is usually lined with ileal mucosa. In approximately 25 per cent of the cases, however, heterotopic mucosal variations have been observed. Typical mucositis of the gastric or jejunal types and pancreatic tissue are the chief variants seen. Gastric mucosa occurs oftenest at the neck of the diverticulum, and it is thought that the secretion of hydrochloric acid by the mucosal glands disposes to erosion, ulceration and hemorrhage at this site.

Pathologic changes, occurring in 25 to 33 per cent of the cases (Nygaard and Walters<sup>1</sup>), may be described as mechanical, inflammatory, heterotopic and neoplastic. The contents may undergo decomposition, especially if the neck of the diverticulum is narrow. Gangrene and obstruction may result from volvulus or invagination of the diverticulum into the ileum to cause intussusception. Inflammatory changes may predominate, as in idiopathic diverticulitis with regional peritoneal irritation, and in later stages, perforation and diffuse peritonitis. Peptic ulcer arising in aberrant gastric mucosa is the more prominent disturbance associated with heterotopic tissue formation. The ensuing intestinal hemorrhage may be depleting and severe. Neoplastic changes in the diverticulum have been observed in the form of myoma, lipoma, neuroma, papilloma and carcinoid as benign growths, and sarcoma and carcinoma as malignant growths, with and without metastases to the mesenteric nodes.

The greater number of diverticula are uncomplicated, cause no symptoms, and are found incidentally at operation or autopsy; they rarely contain heterotopic tissue. The varied complications give rise to no single, characteristic syndrome. Nevertheless, a revealing, more or less definite symptom complex may be seen in the major types of lesions. Pain, soreness or tenderness is present in approximately 50 per cent of the cases. The pain is usually intermittent, colicky and moderate, and occurs chiefly in the right lower abdomen. The tenderness is often localized to the right or left of the umbilicus.

Symptoms of obstruction have arisen more commonly from intussusception and adhesive bands,

either inflammatory or connecting the diverticulum to the umbilicus, thus obstructing a loop of adjacent bowel. Volvulus is much less common. Over 170 cases of intussusception due to an invaginated Meckel's diverticulum have been collected and reported (Halkins<sup>4</sup> and Greenblatt et al.<sup>5</sup>). In addition, inflammatory lesions may lead to adhesions between the diverticulum and bowel, resulting in obstruction.

The symptomatology of the diverticulitis group simulates that of appendicitis, except that the tenderness has often been localized at or to the left of the umbilicus. Unless the appendix has been previously removed, it may be impossible to differentiate diverticulitis from appendicitis. This will not delay the institution of proper treatment, however, for such a syndrome should lead to early surgical intervention in both situations.

The peptic group<sup>6</sup> may simulate the peptic-ulcer syndrome, the symptoms depending on the presence of ulceration, hemorrhage or perforation, with peritonitis. Intestinal hemorrhage has been found to be the essential finding, and often the only one, of this group. Acute anemia may result. Vague to definite periumbilical pains, often related to meals and associated with past or recurring intestinal hemorrhage, suggest the diagnosis. Not every case of ulceration has hemorrhage, perforation or pain, yet all three may be present.

The chief symptoms arising from an umbilical fistula are soreness, tenderness and a mucopurulent or fecal discharge. The diagnosis rests between a persistent omphalomesenteric duct and patent urachus. If a fecal fistula is present, the latter is more certainly excluded.

Tumors arising in the diverticulum cause indefinite primary symptoms referable to the tumor itself, and more pronounced secondary symptoms arising from superimposed complications. Lower abdominal distress and intermittent, moderately severe, cramplike pain have been found in 50 per cent of the cases. Frequently, the pain may be referred to the epigastrium. The tumor was palpable in 5 of the 20 cases reviewed by Nygaard and Walters<sup>1</sup>. Two of these were revealed by pelvic examination. Mention is made of the tendency for the tumor to slip away from the examining hand. Generally, symptoms and signs depend not so much on the size of the tumor as on the secondary complications, such as bleeding, intussusception, obstruction, perforation and local or diffuse peritonitis. In most of these patients, preoperative x-ray studies of the passage of barium through the small bowel have not been employed because of the signs of an acute inflammatory condition. Consequently, the literature on the positive roentgenologic findings has

been meager. In the less acute cases, however, serial studies of the small bowel—namely, films taken hourly for five hours after administration of the barium—may demonstrate the lesion. In 6 of the 22 cases of malignant disease reported to

There had been no previous operations, and no significant loss of weight.

Examination revealed a well-preserved woman, who appeared moderately ill and complained of lower abdominal pain. The temperature was 99.8°F., the pulse 92, and the respirations were normal. The abdomen was

date, the diverticular lesion was demonstrated roentgenologically.

#### CASE REPORT

Mrs. M.K., a 48-year-old Greek-American housewife, was admitted to the New England Baptist Hospital, under the care of Dr. Peter Comanduras, on November 24, 1940, with a chief complaint of abdominal pain of 3 days' duration. Except for intermittent abdominal discomfort for 17 years, for which she had had much medical care, the patient had been well.

For 3 days, there had been general abdominal pain of slight severity. This became worse 24 hours before admission and shifted to the lower abdomen, with tenderness and discomfort in both lower quadrants. There had been gradual development of slight distention and borborygmi, but no nausea, vomiting, constipation, diarrhea, fever or chills. The menstrual history was irrelevant.

moderately rounded and tympanitic, with definite but not marked distention. There were diffuse soreness and tenderness in both lower quadrants, without localized signs. Spasm was voluntary, and no mass was palpable. Manipulation of the uterus bimanually caused lower abdominal pain. However, there was no adnexal mass or tenderness, and there was no mass in the rectouterine pouch of Douglas.

The white-cell count was 9000, and urinalysis was normal. A diagnostic x-ray plate of the abdomen showed a moderate amount of air in the stomach and a lesser amount in the large bowel. There was no small-bowel distention. Gastrointestinal x-ray studies during the previous year had been reported as normal, and had not shown the presence of either a tumor or a Meckel's diverticulum. The clinical picture was regarded as atypical, and the tentative diagnosis of an acute surgical condition of the abdomen, probably acute appendicitis, was made.

Operation on the evening of admission by one of us (H. L. A.) was carried out through a right-lower-quadrant paramedian incision, with retraction of the rectus muscle laterally. A moderate amount of brown, turbid fluid without odor was encountered, culture of which produced no growth. Exploration revealed the viscera, including the large and the small bowel, to be normal except for the terminal ileum, 20 cm. from the cecum. On delivery of this portion of the bowel from the pelvis, there was a gush of yellowish exudate, resembling pus, but still without odor. At this part of the ileum, and arising 1 cm. from the mesenteric border, there was a firm, tensely filled, whitish, cylindrically-shaped 4-by-3-by-3-cm. mass, with markedly enlarged lymph nodes in the regional

somewhat soft and dark red. On opening of the bowel, the mucosa is entirely normal except for an opening 0.2 cm. in diameter. This communicates with a central lumen in the mass which projects into the mesentery. On section, this mass has a well-developed muscularis and a serosa, and is lined by mucosa continuous with mucosa of the bowel. From its base, an irregularly polypoid growth, covered with greenish exudate, protrudes into and practically fills the lumen. On section, this polypoid growth is 1 cm. thick, and shows gray, fibrous tissue, with scattered foci of necrosis extending out to the serosa, which at this point is yellowish gray. The remaining mucosa of the diverticulum is of normal thickness and communicates smoothly with

FIGURE 2.

mesentery. The adjacent nodes were hard and grossly carcinomatous, whereas the more distant nodes at the root of the mesentery were soft and edematous in appearance.

Resection of 30 cm. (12 inches) of the ileum was carried out, including a margin of 10 cm. of ileum on each side of the lesion. A V-shaped portion of the corresponding mesentery and enlarged lymph nodes was included in the resection. End-to-end anastomosis of the ileum was done, with the use of the Furness clamp. Precautionary ileostomy was performed by inserting a No. 20 catheter in the ileum 15 cm. proximal to the anastomosis. The catheter was then brought out through the omentum and a separate small stab incision in the abdominal wall. The incision was closed without drainage.

The pathological report by Dr. Shields Warren was as follows:

The specimen consists of a portion of ileum with adjacent mesentery, 30 cm. in length, which is essentially normal except for a firm and reddish mass, 3.5 cm. in diameter, extending into the mesentery (Fig. 1). The surface is smooth and rounded. Nearby, in the mesentery, is a firm, dull-gray mass measuring 3 by 2 by 2 cm., and a third mass 2 by 1 by 1 cm., which is

the mucosa of the ileum. The larger mass in the mesentery, on cut section, is homogeneous and yellow gray. The smaller mass, on section, is reddish gray and hemorrhagic.

On microscopic examination, the diverticulum is seen to have a well-developed muscularis; in the region of the tumor, this is heavily and irregularly infiltrated by masses of epithelial cells, which, in most places, form irregular glands (Fig. 2). Much of the inner aspect is completely necrotic and infiltrated by polymorphonuclear leukocytes and fibrin. Some of the tumor has penetrated the muscularis and is growing out into the mesentery. The cells of the tumor are irregularly but frequently cuboidal, or low columnar, and contain scattered mucous ductlets. The nuclei are oval and moderately vesicular, with usually a single prominent nucleolus. Mitoses are fairly frequent. In the diverticulum, there is no evidence of gastric mucosa.

Sections of the mesenteric masses show similar tumor tissue, with varying degrees of necrosis.

Diagnosis: adenocarcinoma arising from Meckel's diverticulum, with metastasis to two lymph nodes.

Convalescence was normal until the 11th day, when removal of the ileostomy tube was followed by brisk hemorrhage through the stab incision, which had been made

too close to the left inferior epigastric artery. The hemorrhage was controlled by a tight pressure dressing, however, without further intervention. The patient was discharged on the 21st postoperative day.

She has been seen periodically since then, the last visit being in June, 1941, 7 months after operation. A check-up gastrointestinal x-ray series, 3 months after operation, revealed a well-functioning anastomosis. At the last visit, the patient's general health was good, and there was no evidence of recurrence or metastasis.

This is the seventh case of carcinoma arising in a Meckel's diverticulum that we have been able to find reported in the literature. Most of these reports have been made in recent years. The previous 6 cases were reviewed by Nygaard and Walters<sup>1</sup> in 1937 (Table 1). Only 1 case, that re-

TABLE 1. Cases of Carcinoma Arising in Meckel's Diverticulum Reported in Literature from 1931-37.

AUTHOR	AGE OF PATIENT yr.	TYPE OF NEOPLASM	TREATMENT
Wiseley <sup>8</sup> (1931)	41	Medullary carcinoma	Removal
Copeland <sup>9</sup>	?	Adenocarcinoma (? of umbilicus)	Removal

Brown <sup>12</sup> (1933)	62	Medullary carcinoma	Removal
Gray and Kernohan <sup>7</sup> (1937)	37	Adenocarcinoma (arising from gastric mucosa)	Removal

ported by Gray and Kernohan,<sup>7</sup> showed the adenocarcinoma arising from gastric mucosa within the diverticulum.

In all 7 cases, removal of the diverticulum, tumor and regional metastatic areas was carried out, with reasonable expectancy of immediate salvage of these patients. Although more information regarding the late results in these patients would be helpful, it seems from this experience that the malignant tumor manifests no more rapid rate of growth than carcinoma of other portions of the intestinal tract. It also seems evident that the local complications usually produce symptoms early enough to allow timely radical resection of the growth before widespread dissemination occurs.

The need for generous resection of both intestine and mesentery well lateral to the growth is emphasized, to include any lateral lymphatic extension of the metastases around tumor-blocked lymph channels in the mesentery.

Reports of sarcoma arising within a Meckel's diverticulum have been more frequent, with 16 cases reported in the literature (Skinner and Walters<sup>2</sup>). Clinically, these sarcomas differ little from the carcinomas in that both give rise to symptoms when such complications ensue as ulceration, hemorrhage, obstruction by pressure or intussusception, and perforation. The sarcomas have usually been much larger primary tumors than the carcinomas, but most have been likewise resectable.

SUMMARY

Increasing clinical recognition of the many possible complications that may arise in a Meckel's diverticulum continues to stress the value of early control of these complications and even removal of the uncomplicated diverticulum whenever feasible. In the majority of cases, the complications are acute, and the diagnosis is uncertain or unsuspected. The responsibility therefore often lies heavily on the surgeon to recognize the lesion at operation, as in our patient. This may be difficult in the presence of marked obstruction, peritonitis or a large tumor, with or without metastases. Attention has been directed here to the occurrence of malignant neoplasms arising in a Meckel's diverticulum, more particularly to carcinoma, with the report of a case in which the growth was removed and an immediate successful outcome secured.

## MEDICAL PROGRESS

### GYNECOLOGY: ENDOMETRIOSIS

JOE V. MEIGS, M.D.\*

BOSTON

IN this review, endometriosis and adenomyosis are considered two separate entities. Endometriosis is used to describe widespread areas of ectopic endometrium; an endometrioma is a single area of ectopic endometrium. Adenomyoma indicates the growth of tissue from the true endometrium into the myometrium, whereas adenomyosis indicates a diffuse involvement of the uterus. This is not an absolutely accurate division but, for the purposes of this review, will suffice. Adenomyosis is a fairly clear-cut entity with a satisfactory explanation, whereas great controversy still rages concerning endometriosis. Cullen<sup>1</sup> has shown that most uterine adenomyomas are due to the direct downward growth of endometrium into the myometrium, and direct connections were demonstrated in most of his cases. Adenomyoses or adenomyomas are often responsible for dysmenorrhea and abnormal bleeding, and are more frequently found in patients who have had many pregnancies rather than a few, in contrast to endometriosis. Adenomyosis is usually found in older women and is often reported from the laboratory when not suspected clinically. The treatment is, as a rule, removal of the uterus. Sometimes, adenomyomas are found as diffuse, fibroidlike areas in the uterus, but without capsules; they appear to be fibroids, but do not shell out of the myometrium as fibroids do. An adenomyoma is microscopically similar to an endometrioma.

Endometriosis is a very live topic principally because of Sampson's<sup>2-4</sup> epoch-making studies and, more recently, because of its apparent increase in frequency<sup>5</sup>—whether this is an actual increase or not, it is as yet impossible to state. Experimental work on the problem has been carried out and will be described later, but its true explanation is not yet established. Associated as it is with infrequent child bearing and sterility, it is of great importance to all. Endometriosis or endometriomas may be found in many areas, but nearly all are pelvic or close to the pelvis. The disease is rarely found outside the organs and peritoneum of the true pelvis, and yet there is no acceptable

reason why it should not be. Endometriosis has been found in the arm, the lung, the leg, the round ligament in the inguinal canal, the vulva, the cervix and the perineum, and the explanation of these lesions has not been satisfactory. All the pelvic organs and parts of the pelvic peritoneum have been involved, some for one reason and some for others.

#### SYMPTOMS AND DIAGNOSIS

The symptoms of endometriosis are well known. They may or may not consist of a definite group, or any one of the usual symptoms may be present, or there may be none at all. Typically, the patient complains of painful menstruation or at least of menstrual pain, abnormal flowing, a change in the type of period or backache. Examination may be negative, or there may be masses in the broad ligaments or nodules in the uterosacral ligaments when the patient is examined by rectum. A hard beady or shotty feeling in the cul-de-sac on vaginal or, especially, rectal examination may suggest the correct diagnosis. There has been very little new progress in the evaluation of symptoms or physical examination. Special nodules, such as those occurring in the vulva, groin, umbilicus and abdominal scars, frequently swell before the menstrual period, and this swelling with a definite rhythm usually makes the diagnosis easy. Lesions in the rectovaginal septum may be seen as red, buttonlike areas or as a conglomeration of blue spots; the diagnosis is easy if considered. Endometriosis of the bowel is never difficult to diagnose, for bleeding may occur and is usually rhythmic. The tumor is often behind the mucous membrane, and the x-ray picture may show uninjured bowel mucosa. The presence of acquired dysmenorrhea or premenstrual pain and the occurrence of a mass are very significant, and at operation the finding of characteristic puckered areas with blue spots or the presence of pelvic endometriosis should clinch the diagnosis of endometriosis in the bowel.

#### TREATMENT

There has been no outstanding contribution to the treatment of endometriosis. For years, it has been known that removal of the ovaries or their destruction by means of radiation stops the growth

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C. Thomas Company, 1941, \$4.00).

\*Instructor in surgery, Harvard Medical School, chief of Gynecologic Service, Massachusetts General Hospital; gynecologist, Pondville Hospital.

of the tumors and allows atrophy to take place, as it does in the endometrium itself. The radical treatment is total hysterectomy, with bilateral salpingo-oophorectomy, and the conservative treatment is to excise the areas in the ovaries, peritoneum or other accessible places. If, after conservative treatment, recurrence takes place, radium or x-ray therapy will destroy the ovarian hormone output, and the lesions will atrophy. Excision of the small peritoneal lesions has long been carried out, and some observers have recently recommended the fine nasal cautery to destroy each of the small implantations found on the peritoneum. Since Cotte<sup>6</sup> advocated resection of the superior hypogastric plexus (presacral nerve) for dysmenorrhea, it has been obvious that this operation should be tried to check the pain of endometriosis; it has been advocated by many.<sup>7, 8</sup> Counseller<sup>9</sup> has lately changed his ideas and suggests its use only in cases of uterine adenomyosis, because from the knowledge of the areas affected by this nerve plexus it is unlikely that resection would stop the pain of endometriosis involving the broad ligament or other pelvic structures. Section of the nerve involves the uterus only, and therefore should relieve only uterine pain. Cooke<sup>10, 11</sup> has recognized this and carries out ovarian neurectomy to relieve ovarian pain by cutting the infundibular pelvic ligaments—the best way to section the sympathetic nerves of the ovary. If there is no damage to the ovary by interfering with the blood supply, it is much more reasonable to expect relief by this method than by resection of the presacral nerve.

The use of hormones to suppress menstruation completely by interfering with the pituitary gland should help, but such treatment cannot be carried on long enough to obtain any permanent result. Testosterone will suppress menstruation for months, but may cause growth of hair if too much is used, or if it is employed for too long a period. It is therefore not advocated. Estrin, which has been given to prevent ovulation<sup>12</sup> and thus prevent true or uterine dysmenorrhea, should prevent the pain of adenomyosis, but it should not affect the lateral masses of endometriosis that are responsible for flank pain. Sturgis<sup>13</sup> believes that the pain of endometriosis may be due to the premenstrual congestion that nearly always precedes menstruation and thus causes swelling of scarred and fibrotic endometrial lesions. Prevention of ovulation with estrin would not prevent edema, but testosterone, by inhibiting the pituitary gland and therefore all action on the ovary, will prevent edema and therefore eliminate painful swelling.

Treatment of endometriosis should therefore con-

sist in conservative surgery, with the destruction or removal of small areas of ectopic endometrium in women desiring children, or radical surgery in the older age group—that is, by removal of all involved tissue, with the preservation of ovarian function, radiation being used if growth continues. It is well to caution the operator who attempts to do a total hysterectomy to remember that in these cases the posterior cul-de-sac and the rectum may be pulled up and frozen to the back of the uterus at the level of the internal os; an attempt to free this cul-de-sac to allow an approach to the cervix may result in a hole in the bowel. It is far wiser, if one is confronted with an extensive case of endometriosis with its tough adhesions, to remove all tumor and organs that can easily be removed, and trust to radiation later, than to perforate the bowel in an attempt to do a radical removal.

#### RESULTS OF TREATMENT

The results of radical treatment are excellent. The subsequent menopause can be treated satisfactorily by ovarian hormones, although this treatment may stimulate the growth of remaining endometrial tissue. Conservative treatment results in from 9 to 26 per cent of reoperations.<sup>7, 14, 15</sup> Inasmuch as most conservative operations are done for preservation of childbearing, it is essential to note that from 9 to 32 per cent of patients<sup>14, 16, 17</sup> become pregnant subsequent to operation. There is no doubt of the value of conservative procedures, but it should always be explained to the patient that there is a definite possibility of radiation or further surgery. The relief of pain following conservative surgery is great, but in some cases, early reoperation has been necessary, and in others, late. The endometriosis progresses slowly but steadily under the influence of the ovarian hormone, estrin.

#### ETIOLOGY

The greatest interest in this entity concerns the theories of its etiology, about which many controversies still rage. The main one concerns whether Sampson's theory of tubal reflux is correct or not.

Of first importance is the fact that endometriosis or adenomyosis is a comparatively newly recognized entity. In 1897, Cullen,<sup>18</sup> at a meeting of the Johns Hopkins Hospital Medical Society, reported his first case of adenomyoma of the uterus. In 1897, Pfannenstiel<sup>19</sup> reported the first case of adenomyoma of the rectovaginal septum. Russell<sup>20</sup> reported, in 1899, the finding of endometrial tissue in the ovary; he also removed a

small, pea-sized nodule of endometrial tissue from the right uterosacral ligament. In 1918, Cullen<sup>1</sup> operated on a patient with an adenomyoma of the rectovaginal septum and a widespread growth of the sigmoid. In 1909, Meyer<sup>21</sup> reported the history of a patient, operated on by Mackenrodt for adenomyoma of the bowel, who had had a resection done. In 1921, Sampson<sup>2</sup> reported his first group of patients with perforating hemorrhagic cysts of the ovary and demonstrated the presence of endometrial tissue in them and in the pelvic peritoneum. In 1922, Janney<sup>22</sup> reported a group of patients with endometrium in the ovary. From the time of Sampson's first report, the literature has teemed with articles on endometriosis, a partial list of which is appended at the end of this review. Sampson has written by far the most numerous and most carefully prepared papers and has given not one but numerous theories of its development. However, the one that is usually regarded as his greatest contribution concerns the question whether or not endometrium can flow through the tubes during menstruation and become implanted on the ovary and peritoneum of the pelvis. Since Sampson's great paper, many other ideas of the etiology have been presented.

The theory of von Recklinghausen that adenomyosis and endometriosis are due to growth of left-over pieces of the Wolffian ducts has long been discarded. It is far likelier that these conditions arise from cell remnants following the formation of the Mullerian ducts. This will be discussed later. Ivanoff<sup>23, 24</sup> and Meyer<sup>25</sup> independently advocated the idea that the epithelium of the pelvis, inasmuch as it is the celomic epithelium from which the Mullerian ducts arise, can under certain circumstances, such as irritation due to inflammation or injury by menstrual blood, undergo metaplasia and produce Mullerian epithelium or endometrium. This theory is plausible and has many advocates. It explains most endometriosis satisfactorily. Heim<sup>26</sup> supports this theory by stating that endometriosis occurs only in tissue that is derived from the original celom. He believes that it may be derived from the mesothelium, endothelium or germinal epithelium of the early embryonic celomic cavity. Bell<sup>27</sup> and Robinson<sup>28</sup> actively join the theory of Ivanoff and Meyer, both believing that the celomic epithelium under certain circumstances may be the source of the ectopic endometrium.

Halban,<sup>29, 30</sup> in 1924, advanced the idea that pieces of tissue metastasized by way of the lymphatics, and suggested that the sites of endometriosis were best explained by lymphatic routes. It is true that this theory best explains the presence of endometrial glands in lymph nodes of the pelvis. In

operations for cancer of the cervix, such lymph nodes have been found and described. Taussig<sup>31</sup> has recently found such nodes in cases in which he has done pelvic lymph-node dissections following radiation treatment of cancer of the cervix. This method of extension of endometriosis may best explain the report of Büngeler and Fleury-Silveira<sup>32</sup> of endometriosis in the pleural cavity; however, extension to the chest cavity may also be explained by metastasis through the blood stream.

Sampson's various theories, some not generally known, are as follows:

During menstruation, pieces of tissue are cast off, and some of this tissue may flow in retrograde method through the tube and, being spilled out, may grow on the ovary or the peritoneum, where such particles may alight.

Pieces of endometrium may grow into the wall of the fallopian tube, or may be caught in the fimbrias of the tube and grow there.

The tubal mucosa itself may act in response to the ovarian hormones and may occasionally menstruate, and pieces of tubal epithelium may be implanted by contiguity on the ovary or any other structure it may touch.

An ovarian endometrial blood cyst may rupture and spill pieces of endometrium into the pelvis that may grow—Sampson agrees that there is no positive proof of this.

An endometrioma of the ovary may become attached to a pelvic structure, and because of the adherence to the peritoneum, areas of endometrium may grow into the contiguous peritoneum.

Cast-off endometrium may go so far as to implant itself in a hernial sac and thus may account for endometriosis in the groin found in a hernial sac.

It can also spread by way of the lymphatics and blood vessels, and thus find its way into the round ligaments.

There are many reasons for Sampson to believe in his major theory, for he has seen what he considers viable endometrial tissue surrounded by blood in the material flowing through the tubes at laparotomy. The lesions of the ovary are on the lateral and under surfaces, an especially good place for blood to strike the ovary as it comes out of the tube. He believes that peritoneal implants are so small that they do not participate so perfectly in menstruation as ovarian endometrial cysts. He also believes that, if the bits of endometrium carried into the pelvis through the tubes are dead, his theory is dead. His theory has support from the work of Bartelmez,<sup>33</sup> who on examining uteri removed and fixed immediately after laparotomy says that even the tissue fragments and cell masses free in the lumen on the first day of the menstrual flow have many cells that appear normal histologically. Such support is very satisfactory. However, the work of Markee<sup>34</sup> is extremely damaging to Sampson's theory. Markee transplanted living endometrium of the uterus of the monkey into the eyes of the same monkey and obtained a

very large percentage of takes. By this method, he was able to view menstrual cycle after cycle either by the naked eye or by microscope. He makes the following observation: "Although thousands of fragments were observed in the 432 menstrual periods studied since 1928, not a single re-implantation of a fragment was noticed. It was seen that the fragments settled to the bottom of the anterior chamber [of the eye] and disintegrated. Occasionally one would remain whole for 36 hours but most of them disappeared within one hour and many within 30 minutes." This suggests that, in the monkey, endometriosis cannot be due to the implantation of such fragments, which are not viable, at least not in the anterior chamber of the eye, although Cron and Gey<sup>35</sup> reported a growth of desquamated fragments in tissue culture. The work of Cron and Gey, to which a great deal of weight has been given in the past in support of Sampson's theory, is of questionable value, for the tissue that was grown on a plasmatic medium consisted of pieces of tissue obtained from a woman on the second day of the menstrual cycle that were removed by a *dull curette*. Leukocytes and connective cells and sheet-like outgrowths of epithelial cells were grown. The tissue was transplanted every four or five days for a month, but no increase in the mass of tissue occurred. In a footnote on the same paper, the authors state: "... additional experiments show that the fragments of epithelium [decidua menstrualis] normally found in the menstrual flow and obtained without the use of a dull curette, are visible. In general, as far as we have been able to determine, the decidua menstrualis, is more active when cultured in vitro than normal endometrium." No further reports have been found in the literature concerning the results of these later tissue cultures to enlarge on the footnote, and it is obvious, in view of Markee's work in the monkey, that this should be done, for proof is not present in the reported experiment.

In answer to the problem raised by Markee's work, many would say that the tissue of the eye is not similar to that of the pelvis, and yet it was possible to transplant endometrium into the eye easily. The work of Jacobson<sup>36</sup> demonstrates that the endometrium of the rabbit and the monkey will grow in the pelvis of those animals, more especially if the peritoneum of the pelvis is irritated or if the tumor is transplanted into the pelvic peritoneum. But such tissue will *not* grow in the remainder of the peritoneal cavity. Moreover, Jacobson found in some of his experiments that endometrium would grow after the ovaries were removed. However, the endometrium used was a transplantation, such as a skin graft and not an

implantation as one understands Sampson's theory, and it is difficult to explain how implantation could occur in the human being unless some irritation of the peritoneum had occurred. The tissue used by Jacobson in his work was viable endometrium and not cast-off menstrual tissue. His difficulty with such material, and his ability to grow it only in the pelvis and Markee's difficulty with the eye make one think that perhaps the pelvic epithelium has some special value as a grower of endometrium or that it has in itself the inherent power to growth, and that the areas of endometriosis are responses to injury, as suggested by the Iwanoff and Meyer theory, rather than true implantations. It is obvious that more investigation must be done along the lines of Cron and Gey and of Jacobson before Sampson's theory of the growth of cast-off endometrium can be accepted. In about half the cases, the small peritoneal implantation functions as the endometrium does; in the other half, the endometrioma resembles the basal layer of the endometrium, which does not function. If Sampson's theory is correct, it seems that, since the endometrium cast off by the uterus must have been from the functional layer (compact layer), its implantation in the pelvic peritoneum should function and should not appear or act like the basal layer. Perhaps the cast-off functional tissue becomes the nonfunctional basal type. It seems, however, as if this suggested that the two tissues, cast off endometrium and implant, are not the same.\*

There are three other recent reports of interest in the consideration of ectopic endometrium. Büngeler and Fleury-Silveira<sup>32</sup> report the presence of endometriosis in the pleural cavity, Naratil and Kramer<sup>37</sup> of endometriosis in the extensor carpi radialis muscle of the forearm, and Markee<sup>38</sup> of endometriosis in the left thigh. The explanation of the chest-cavity extension, as noted above, is probably by extension through the lymphatics or veins of the vascular system, but that of the thigh and arm cannot be explained on any other basis than extension by vein. Hobbs and Bortnick<sup>39, 40</sup> have shown that viable endometrium can be transplanted to the lungs by way of the veins and that it will grow in the lungs. This is experimental proof that venous metastasis is a possibility. Until the excellent work of Batson,<sup>41</sup> it has always been impossible to explain the extension of tumors from the pelvis to bones and certain organs except through the lung, which presupposes the growth of a metastasis in the lung and subsequent extension to the left heart, or the

\*On the other hand, Sturges<sup>33</sup> believes that function depends on blood supply and hence a satisfactory supply of estrin, and that the functional endometrium that implants itself in the pelvis may be nonfunctional if the blood supply is not sufficient.

presence of an open foramen ovale in the heart. Too many unexplained metastases occurred, and the work of Batson, who has demonstrated a vertebral venous system, has unraveled the difficulties. This system of veins leads directly from the pelvic organs to the bones or, by connecting veins, to the veins of the extremities, without going through the caval system. In this way, the lungs can be detoured, and an endometrioma in the leg and arm and possibly one in the pleural cavity can be explained. These cases and Batson's work are in support of those who believe in the venous metastatic theory of endometrial extension. If the cases with endometrioma in the leg and arm are authentic, and it seems as if they are, the possibility of venous metastasis is a very significant theory of endometriosis.

It has always been difficult to explain why the small endometriomas seen in the pelvis are, when not accompanied by ovarian endometriosis, usually in the midline. Certainly, the uterosacral ligaments are difficult places for cast-off endometrium to light on and grow, as is also the area at the reflexion of the bladder flap on the uterus. Yet these areas are frequently affected. Such cases are better explained by the development of embryonal rests in the celomic epithelium or by venous or lymphatic metastasis. If endometriosis is due to the reflux of endometrium in menstrual fluid, the absence of tumors on the anterior abdominal wall and among the intestines and in the mesentery is

greater percentage of endometriosis in private practice among well-to-do patients than in the wards of the Massachusetts General Hospital. It was suggested that the reason for this was earlier marriage and earlier childbearing in the hospital group than in the private group. It was thought that birth control and spacing of children were having a serious effect on the fertility of well-to-do young women. Lack of early marriage and childbearing in young women is serious, for endometriosis is often accompanied by infertility. Monkeys in the jungle mate as soon as they become of age and have offspring until they either physiologically cannot have any more or die, but some women go at least twelve years without interruption of their menstrual periods. This is not normal. Twenty-eight per cent of 400 private patients had histologic endometriosis, in contrast to only 5 per cent of the ward patients at the Massachusetts General Hospital (Table 1). Only 66 per cent of married women with endometriosis in private practice were fertile, whereas 94 per cent of the hospital patients were fertile (Table 2). Seventy-three per cent of the private and 42 per cent of the hospital patients had two or less children; 53 per cent of private and 12 per cent of hospital patients were twenty-five years of age or over when married. Sixty-five per cent of the private patients, and only 40 per cent of the hospital patients, who had endometriosis had menstruated over ten years before the first pregnancy. All in all, there is a

TABLE 1. *Incidence of Endometriosis.*

hard to explain. Although the pelvis is the likely place for endometrium to rest when a woman is upright, it is not the dependent area in a woman lying on her stomach. A woman is quiet when sleeping, she menstruates when asleep, and at that time a reflux would be likelier, and implantation should occur more easily. Because endometriosis is not found in ventral areas and is nearly always in the pelvis, it is probable that the pelvic epithelium or celom has some special predilection for this lesion.

It was recently shown<sup>5, 42</sup> that there is a much

great difference between these two groups, and the great amount of endometriosis in the private group can be explained on the basis of delay of childbearing. These facts are evidence that menstruation during many years without interruption is the cause of endometriosis, and that it is due to the stimulation to growth of the celomic epithelium and its embryonal rests.

Another striking fact is that underdevelopment of the genital organs is a frequent accompaniment of endometriosis. Patients with congenital erosion of the cervix, severe dysmenorrhea and

juvenile organs are very apt to develop endometriosis earlier than those without such stigmas. This suggests that if the uterus and the cervix are underdeveloped, so also may be the pelvic peritoneum; such patients are thus likelier to harbor embryonal rests and therefore more frequently have endometriosis. Late childbearing may allow more years of reflux bleeding, but the problem is more fundamental than that, and avoidance of normal function seems to be the cause. The pelvic or celomic epithelium, which is the only re-

gion that grows endometriosis, is probably stimulated to growth by abnormal physiologic function. It is therefore time to advocate the obvious — namely, that all women should marry early and bear children early.

\* \* \*

Many questions concerning endometriosis are still to be answered. For example, why do areas of ectopic endometrium menstruate when Bartelmez and Markee and others have shown that menstruation is such a complicated process, necessitating coiled arteries of a special type and the varied layers of the endometrium? Why does pain occur when the uterus is not involved? Why is it that small endometriomas in the peritoneum do not become large chocolate cysts? Why is endometriosis localized in the pelvis in nearly all cases? Can cast-off endometrium grow?

In recent years, the work of Batson demonstrating a vertebral venous system has been outstanding because it explains, by a detour around the lungs, the method of extension of malignant lesions as well as of endometriosis. The work of Markee and Bartelmez aids in the conception of menstruation and leaves a great deal of explaining to account for the action of ectopic endo-

metrium. The work of Hobbs and Bortnick, by showing the viability of endometrium after venous extension to the lungs, is of great value. Cron and Gey's work should be repeated in a larger series of cases, for their experiments do not seem to be proved. The fact that ectopic endometrium has been found in the pleural cavity, the arm and the leg suggests that the theory of the venous pathway for extension of endometrium may be correct. Finally, the great frequency of endometriosis in private practice as distinguished from hospital-ward cases makes the questions of late marriage and late childbearing of great significance.

Progress has been made in the understanding of these lesions, but a great deal of work remains to be done.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 28041

#### PRESENTATION OF CASE

*First admission.* A thirty-three-year-old Lithuanian-American housewife entered the hospital because of increasing dyspnea.

She had been quite well until a year and a half before admission, when dyspnea on exertion developed insidiously, accompanied by a vague feeling of substernal oppression. Six months before entry, slight cyanosis began to accompany the episodes of dyspnea. The patient began to sleep with an extra pillow, and experienced occasional nocturia. Six weeks before she entered the hospital, a physician gave her "heart pills," which she took for two weeks, without improvement in her condition. She then noted for the first time that her legs and abdomen were swollen, and that she had gained 30 pounds in weight. Additional pills "for the edema" were given by the physician, without noticeable effect.

Prior to the onset of her illness, the patient had often taken long walks without difficulty. She had had "pleurisy" thirteen years before. She denied syphilitic or rheumatic disease and had never been told of any cyanosis or functional disability in infancy. Two siblings had died in infancy of unknown causes, and her father had died at fifty-four of a "heart attack." She had been married for thirteen years but had never been pregnant.

Examination showed an obese, plethoric, quite cyanotic woman in moderate respiratory distress. The heart was enlarged, especially toward the left, with a diffuse apical impulse. The rhythm was regular. The heart sounds were distant, with accentuation of the pulmonic second sound. There was a systolic murmur, best heard at the left border of the sternum. The lungs were normal. The abdomen was distended, and slight shifting dullness was present in the flanks. The liver and spleen could not be felt. There was pitting edema of the lower extremities, and of the abdominal wall below the waistline. There was questionable distention of the veins of the neck. The fingers showed no clubbing.

The temperature was 98°F., the pulse 100, and

the respirations 35. The blood pressure was 140 systolic, 110 diastolic.

Examination of the blood showed a red-cell count of 5,200,000 with 19 gm. hemoglobin, and a white-cell count of 8880 with 73 per cent polymorphonuclears. Oxygen studies of arterial whole blood showed 93 per cent saturation; the carbon dioxide combining power of the plasma was 70.7 vol. per cent. The cell volume was 51.3 per cent. The urine showed ++ to +++ tests for albumin on eleven out of twelve examinations. Only occasional red or white cells appeared in the urinary sediment.

In a roentgenogram of the chest, the heart appeared enlarged, without any characteristic configuration. The left main bronchus seemed slightly elevated. There was fluid in both pleural cavities.

The electrocardiogram demonstrated right-axis deviation. In Lead 1, the QRS complex was slurred, and the T wave was flat. In Leads 2 and 3, the T wave was inverted, with sagging of the ST segment. The PR interval was 0.19 second.

The patient was treated with bed rest, and with restriction of fluid and salt intake. Rapid digitalization was accomplished, and Mercupurin was given intravenously every few days. An oxygen mask was used almost constantly at first, with marked improvement in the cyanosis. The diet was restricted to 800 calories daily, with added thiamin chloride, nicotinic acid and cevitamic acid. There was satisfactory diuresis, the weight dropping from 220 to 165 pounds in the course of a month's stay in the hospital.

*Final admission* (three months later). After the patient's discharge from the hospital, she was followed in the Out Patient Department. The dietary restrictions were maintained, and the patient continued on digitalis. She felt improved for the next two months, after which she was again troubled by cyanosis and dyspnea on exertion. The next week, she remained in bed, taking ammonium chloride. She slept poorly because of orthopnea. Because of increasing breathlessness, she re-entered the hospital.

Examination showed extension of the area of cardiac dullness, which was 15 cm. to the left of the midline at the apex, and 8 cm. at the level of the third interspace. A blowing murmur at the third left interspace filled all of systole. A rushing diastolic murmur was audible at the apex when the patient was placed in the upright position. The pulmonic second sound was split, and louder than the corresponding aortic sound. The border of the liver lay three fingerbreadths below the costal margin. The legs were cold, and

puting edema extended as far as the chest

The blood pressure, temperature, pulse and respirations were approximately as before.

During the night, although the patient was kept in an oxygen tent, she remained cyanotic. Early the next morning, she suddenly began to gasp and died within a few minutes.

### DIFFERENTIAL DIAGNOSIS

DR T. DUCKETT JONES: I wondered briefly if the increasing dyspnea in episodes could have been due to asthma. However, the patient had been examined within a reasonable period of the onset of her illness, and nothing had been found.

The dyspnea on exertion and the vague feeling of substernal oppression were, I presume, early symptoms of left-sided failure.

Cyanosis then assumed a greater part in the picture. The only feature that seems to be left out of the ordinary development of left-sided failure is cough, which the patient apparently did not have.

The swollen legs and abdomen and the increase in weight indicate further progression of heart failure.

"Prior to the onset of her illness, the patient had often taken long walks without difficulty." I suppose that this indicates that she was actually well up to thirty-one and a half years of age, or eighty-eight months before the onset of symptoms.

She had pleurisy thirteen years before admission. The history of pleurisy with pain does not help determine what the actual diagnosis was at the time.

Apparently, congenital heart disease was thought of because of the findings that later developed, and the note concerning well-being in infancy was put in to indicate that there was no evidence early in life of congenital heart disease.

"Examination showed an obese, plethoric, quite cyanotic woman in moderate respiratory distress." There seems to have been more cyanosis than is routinely seen in ordinary heart failure.

"The rhythm was regular." That is very important.

There was a loud pulmonic second sound, at the age of thirty-three. That probably represented some increased pulmonary pressure.

The systolic murmur at this stage means nothing to me; it is not at all unusual in various types of heart disease and in normal hearts. The murmurs described throughout are confusing. Gouley<sup>1</sup> has pointed out that basal systolic murmurs may have some role in pulmonary disease, which certainly comes in as one of the features of differential diagnosis later on in this case.

So far, everything fits congestive heart failure quite well. Why the liver was not felt, I do not know. The ascites apparently was not tremendous, so that one would believe that the liver was not palpable.

"The fingers showed no clubbing." Congenital heart disease in adult life is usually associated with clubbing of the fingers.

I suppose the elevated diastolic pressure might go along with peripheral failure, which the patient obviously had.

The carbon dioxide combining power of the plasma was about 10 vol per cent above normal, which is probably consistent with congestive failure. There was a distinct increase in the cell volume, indicative of hemoconcentration.

In the absence of further reports of urinary sediments and since no blood chemical findings were reported, I presume that the renal picture was the result of congestive heart failure, rather than primary renal disease.

Obviously, there was right-sided and left-sided enlargement of the heart by roentgenogram. The slightly elevated left main bronchus makes one think of a large left auricle, which is frequently associated with mitral stenosis. Both pleural cavities had some degree of fluid, although the amount is not stated.

The electrocardiogram demonstrated right axis deviation. I take it from the original description of this patient that she was not of the stature that would normally have right axis deviation of the heart. She was apparently an obese, short, stocky person, and might conceivably exhibit left axis rather than right axis deviation. Thus, the finding is significant and indicative of right-sided heart damage, of either a temporary or a permanent character.

The inverted T wave and the sagging ST segment suggest that the patient received digitalis shortly before entry into the hospital.

In view of the fact that the majority of patients with congestive failure do not require oxygen therapy, I should assume that the cyanosis was out of proportion to the ordinary features of failure observed in this case.

The restricted diet was probably prescribed on the basis of obesity—to decrease the patient's weight, as well as to get rid of edema fluid by other methods. There is no evidence that the heart status was due to the so-called "beriberi heart."

The patient must have been broad-chested to have a 15 cm left border. The left heart border was obviously well in the axilla, probably with some auricular and left ventricular enlargement.

The murmur of mitral stenosis is not often described as a rushing murmur. I do not know whether the rushing murmur was high or low pitched. I know that the murmur of mitral stenosis is heard better with the patient recumbent in the left lateral position than with the patient erect. I know that a blowing diastolic murmur, from aortic regurgitation, or possibly a basal diastolic blowing murmur, which may be called or considered a Graham-Steele murmur, is heard best in the erect position. Hence, the description of the murmur confuses me considerably. However, one can state that there was a change or progression in the decreased function of the heart in this case.

"The pulmonic second sound was split, and louder than the corresponding aortic sound," again indicative of an increase in pulmonary pressure.

"The border of the liver lay three fingerbreadths below the costal margin." This, together with the extensive peripheral edema, certainly indicates right-sided failure.

This picture is distinctly confusing. There is no history of preceding congenital defects, and many types of heart disease that one thinks of do not fit the picture very clearly. We can comparatively easily rule out the nephritic possibilities; the patient did not have hypertension at the end, and there is no evidence of uremia. The ordinary hypertensive syndrome, with a progressive course over a period of less than two years, would probably have exhibited hypertension at the end, and it is likely that the breaks in compensation would have been more acute and accompanied by more sudden episodes of left-sided failure and generalized symptomatology before the patient would have been bedridden. In addition, she had enlargement of both sides of the heart by x-ray and by physical examination, as well as right-axis deviation, which indicates that there was some right-sided dilatation.

Coronary disease, I think, we can reasonably dismiss. There was no acute episode. This does not always occur, but the patient did not have a low blood pressure at any time. There was never any severe pain, and the electrocardiographic picture is not characteristic of coronary disease.

Cor pulmonale, either acute or chronic, must be thought of. Acute cor pulmonale can be ruled out because there was no severe acute episode indicative of extensive infarction or thrombosis. The patient had no shock, no severe pain and no hemoptysis and she did not have the typical electrocardiogram of an acute cor pulmonale. So far as chronic cor pulmonale is concerned, the possibility of Ayerza's disease, which the cyanosis sug-

gests, can be ruled out on the fact that she did not have so long a period of decreasing pulmonary reserve as is observed in most cases of pulmonary fibrosis. The feature most in favor of cor pulmonale of more chronic form is the right-axis deviation.

Certainly, this is not the picture of syphilitic heart disease.

That leaves a large group of cases of heart disease — the rheumatic. In addition, there remain other types, such as unusual tumors, which I am not qualified to discuss. So far as rheumatic fever is concerned, the patient was fairly young and had had no previous rheumatic history. In rheumatic heart disease discovered for the first time in adult life, mitral stenosis is usually present; it is almost the characteristic feature of slowly or insidiously developing rheumatic heart disease, and is often accompanied by relatively little cardiac hypertrophy. The patients with mitral stenosis who have failure in middle life usually develop auricular fibrillation. In rheumatic heart disease with mitral stenosis for years, with hypertrophy probably as the result of myocardial change of previous attacks of rheumatic fever, there are often embolic phenomena, of which there is no evidence in this case. No murmur of mitral stenosis was heard when the heart rate was 100, and there was no failure. Save for one possibility, I believe we can discard the possibility that mitral stenosis was present. A large left auricle, as suggested by x-ray examination in view of the elevation of the left main bronchus, if practically occluded by thrombus, might occur along with mitral stenosis, even in the absence of the typical murmur. I think this is a possibility, although a remote one. So far as the symptoms of straight rheumatic heart disease and the usual picture of rheumatic fever are concerned, I think they do not exist. Young children or young adults with rheumatic infection who die as a result of acute carditis practically always exhibit right-sided heart failure first and progress to left-sided failure. Evidence of the former develops in the absence of pulmonary symptoms. Such patients do not have dyspnea, and lie flat in bed. The patient under discussion did not exhibit this picture. She had symptoms of left-sided or pulmonary difficulty, in addition to obvious cardiac hypertrophy. Parker and Weiss,<sup>2</sup> in 1936, reported a case of mitral stenosis with pulmonary hypertension, and pulmonary-artery sclerosis, with extensive changes throughout the larger and smaller vessels and arteriolar system of the lung. They considered the changes that they described to be comparable to changes seen in the systemic arterioles in malignant hypertension and

to be capable of developing very quickly in two months. Evidence was presented, aside from the one case given in detail, of the fact that in mitral stenosis there are often changes in lung tissue. Gouley,<sup>1</sup> who has written extensively of the alterations in the lung in rheumatic fever, points out that the pulmonary artery changes are not necessarily constant and dependent on the presence of mitral stenosis. They may be the result of a coincidental vessel and parenchymal change during active rheumatic fever. Gouley describes at great length the rubberoid lungs of chronic rheumatic fever, consisting of a parenchymal thickening and elastic-tissue weakening and hyperplasia. He also describes acute pulmonary consolidation,—so-called "rheumatic pneumonia or pneumonitis,"—which this patient did not have at any time. An acute pulmonary rheumatic process is not essential for such vascular changes to be found at autopsy. In autopsies of rheumatic-fever patients, we have seen practically all the lesions Gouley has described. We have never been entirely convinced that pulmonary changes in rheumatic fever are usually the primary reason for failure in adult life. Except for episodes of acute left-sided failure in adult mitral stenosis, I believe that the valve lesion itself in rheumatic heart disease usually has little to do with failure, but in this case we have a patient with no known rheumatic fever who was ill for less than two years, and who had both right-sided and left-sided failure. If this patient had been fifteen, sixteen or seventeen, it would not have disturbed me too much, despite the fact that there was no clinical evidence of active rheumatic fever—joint pains and so forth. To my mind, there is one syndrome, with changes probably in the heart itself and in the lung, that can produce this picture—namely, a very low-grade rheumatic process. Aschoff bodies may not be found, since the process in the myocardium is a very chronic one and the pulmonary picture is apparently more important than the myocardial. This patient may represent the unusual case in which chronic rheumatic-fever pulmonary changes are of primary significance. My clinical impression is that rheumatic fever could account for this picture, and as a second bet I should say that some unusual type of congenital anomaly might explain the picture.

DR GEORGE W. HOLMES: One or two things brought out in the films are not mentioned particularly in the notes, and I think they will help Dr Jones a little. The extreme narrowing of the supracardiac shadow is very much in favor of his interpretation. I cannot imagine a supra-

cardiac shadow so small as that in the presence of hypertension of any extent. In some of the films, there is evidence of either thickened pleura or fluid, as mentioned in the notes. Nothing was said about this change in the lung itself. I assume that this was attributed to fluid in the pleural space behind the area we are speaking of; however, it does not look like fluid, and one wonders if there was, at some time, some injury to that lobe, such as an infarct. The striking thing about the heart is the dilatation of the auricles.

DR. TRACY B. MALLORY: Does anyone want to hazard another diagnosis?

DR. WILMAN RICHARDSON: I want to hazard one. I think Dr. Jones mentioned it and excluded it, but I wonder whether pulmonary arterial obstruction, possibly on the basis of pulmonary thrombosis, in a patient of this age should not be seriously considered as more likely than rheumatic fever.

DR. JONES: You mean blocking the large vessels?

DR. RICHARDSON: An extending thrombosis.

DR. MALLORY: Dr. Bland, you saw this patient. Should you like to comment?

DR. EDWARD F. BLAND: About once a year, Dr. Mallory presents a very puzzling case of this nature. Several of us had followed this patient's course in the Cardiac Clinic, and she died on the medical ward when I was on service.

There are two important points in the history, whose sequence, I think, needs emphasis: the patient was breathless for a full year before she began to be cyanotic; thereafter, the cyanosis slowly progressed and at the end was extreme. Most of us considered seriously only two diagnostic possibilities: either some unusual congenital anomaly or primary disease of the pulmonary arteries. The clinical course was distinctly against the first and strongly suggested the latter. For the sake of the record, it should be stated that the arterial blood studies on this patient were done after she had been in an oxygen tent, and this alters the results considerably. Throughout her course, the physical signs suggested severe pulmonary hypertension, for which we could find no obvious explanation; we therefore concluded that this was obliterative pulmonary arterial disease and chronic cor pulmonale.

#### CLINICAL DIAGNOSIS

Cor pulmonale.  
Pulmonary endarteritis.

## DR. JONES'S DIAGNOSIS

Rheumatic fever, with extensive pulmonary changes, or  
Possibly, congenital heart disease.

## ANATOMICAL DIAGNOSES

Cor pulmonale.  
Hypertrophy and endarteritis of pulmonary arterioles.  
Infarcts of the lung, small.  
Pulmonary congestion, extreme.  
Chronic passive congestion.  
Peripheral edema.

## PATHOLOGICAL DISCUSSION

DR. MALLORY: It is very easy to cite the anatomic facts, but much more difficult to interpret them. This patient was found to have marked cor pulmonale; the right ventricle was from two to three times the normal size, and despite the marked dilatation, its wall measured 10 mm. in thickness against the normal of 4 mm. The pulmonary conus was distinctly dilated, although the main pulmonary artery was not. The branches within the lung, however, certainly were, and plaques of atheroma were very numerous. When we cut across the lungs, all the small vessels stood out prominently, had obviously thickened walls, and remained patent rather than collapsing as pulmonary arterioles ordinarily do. The lungs were heavy, and considerable amounts of fluid could be expressed from them. The mitral and aortic valves were absolutely normal. There was a slight question of minimal scarring of the tricuspid valve, but it was of normal diameter.

Microscopic examination of the heart showed nothing that would suggest acute rheumatic heart disease. On the other hand, microscopic examination showed the characteristic lungs of mitral stenosis. The alveolar walls were extremely thick and extremely edematous, and all the alveoli were filled with heart-failure cells. The pulmonary arteries were markedly hypertrophied; a few of them were thrombosed, but only a very few. I do not believe that one could claim on a quantitative basis that there were enough thrombosed pulmonary arteries to account for the right ventricular hypertrophy, and the type of change in the pulmonary arteries is much more what I should think was secondary to pulmonary hypertension than an obliterative endarteritis that might be the primary cause of a pulmonary hypertension. The mechanism by which all this is produced is completely beyond me.

DR. HOLMES: Was there anything in the right lower lobe?

DR. MALLORY: A small infarct.

## CASE 28042

## PRESENTATION OF CASE

A twenty-one-year-old Italian-American truck driver entered the hospital complaining of shortness of breath.

He had been well until six months before entry, when he began to tire easily. He felt weak, became dyspneic on slight exertion, and therefore quit work. Three months later, he was troubled with swelling of the face, ankles, penis and scrotum, which progressed until he experienced difficulty in urinating. Because of this, he consulted a physician, who gave him a course of thyroid, with resultant loss of about 10 pounds in weight. The swelling, however, persisted.

Two months before entry here, the patient was admitted to another hospital. His heart was found to be enlarged, extending 11 cm. to the left of the midsternal line in the fifth interspace. The rhythm was regular, with a rate of 51; the sounds were clear. The blood pressure was 112 systolic, 86 diastolic. Extension of the liver edge two or three fingerbreadths below the costal margin seemed likely, but could not be established with certainty, because of the obesity of the patient.

The blood showed a red-cell count of 5,400,000 with 109 per cent hemoglobin, and a white-cell count of 13,300 with 74 per cent mature polymorphonuclears. The blood Wassermann reaction was negative. The blood levels of cholesterol, sugar, nonprotein nitrogen and creatinine and the albumin-globulin ratio were within normal limits. The urine had a low specific gravity, and contained a slight trace of albumin, and occasional red and white cells and casts. Congo-red and phenol-sulfonphthalein excretion tests were negative. The basal metabolic rate was -19 per cent.

A roentgenogram of the chest showed enlargement of the heart involving predominantly the left auricle and ventricle, and an apparent interlobar effusion between the middle and upper lobes of the right lung. A roentgenogram of the skull showed a normal sella. An intravenous pyelogram was negative. An electrocardiogram showed complete heart block, with abnormal ventricular complexes, including marked inversion of the T waves in Lead 4, and a very long QT interval.

The patient was continued on thyroid and was also given ammonium chloride and vitamin B complex. He was kept on a low-calorie diet.

When discharged a month after admission, he had lost 28 pounds in weight and had become free of edema and dyspnea. Following discharge from the other hospital, he remained at home, out of bed, taking thyroid and vitamin B complex. He gradually became orthopneic at night, and began to cough frequently, bringing up fairly large amounts of frothy sputum. Six months after the onset of his illness, and five weeks after discharge from the other hospital, the patient entered this hospital.

An older sister had been studied previously at the same hospital because of the strikingly similar complaints of unexplained dyspnea and edema of the ankles, face and abdomen. Her heart was much enlarged, and in complete block, as shown by the electrocardiogram. The basal metabolic rate was -4 per cent. She was twice tapped for ascites. Death occurred about a year after onset of her illness. At the time the patient entered this hospital, a younger brother was just beginning to complain of dyspnea. He had been gaining weight. Some years previously, a physician found that he had a "large liver," during the course of an appendectomy.

On examination, the patient appeared normally developed and somewhat obese. He was orthopneic, but was not acutely ill. His complexion was ruddy. There was moderate edema of the eyelids, sacral soft tissue and both ankles. There was shifting dullness in both flanks. The liver did not pulsate, and its edge was smooth and was felt three fingerbreadths below the costal margin. The veins in the neck seemed slightly distended. Cardiac dullness extended into the axilla, with a diffuse apical impulse at the anterior axillary line in the fifth interspace. A soft systolic murmur was present at the mitral area. The rhythm was regular. The lungs seemed normal.

The temperature was 100.2°F., the pulse 50, and the respirations 24. The arterial blood pressure was 112 systolic, 80 diastolic. The venous pressure was equivalent to 250 mm. of water, in the right antecubital vein.

Examinations of the blood and urine were essentially the same as those at the other hospital. An electrocardiogram again showed complete block, with an auricular rate of 110 and a ventricular rate of 45. The T waves were flattened. A roentgenogram of the chest was similar to the earlier film, so far as the heart was concerned. There was also an area of increased density in the right cardiophrenic angle anteriorly, adjoining the diaphragm.

The patient became progressively more dyspneic. Three days after admission, Cheyne-Stokes breathing developed. The next day, there were several coughing spells in which the patient brought up

blood-streaked sputum. He complained of pain in the left calf, and the leg was tender to palpation. The temperature varied between 99 and 102°F. On the evening of the fourth hospital day, he had a number of transient convulsive attacks in which his eyes rolled upward and respirations became rapid and gasping. Two hours later, he expired.

#### DIFFERENTIAL DIAGNOSIS

DR. ASHTON GRAYBIEL: The medical history in this case begins with the appearance of symptoms without obvious cause; there is no story of any antecedent illness. Weakness and dyspnea, the first symptoms, were soon followed by massive edema. At that stage of the illness, kidney disease, as well as heart disease, was probably considered. Chronic nephrosis seems to be ruled out by the small amount of albumin found in the urine and the normal albumin-globulin ratio. Similarly, a nephrotic type of glomerulonephritis appears to be unlikely because of the relatively unimportant urinary findings and the normal blood pressure, nonprotein nitrogen and kidney function. Amyloid disease may involve the heart as well as the kidneys and other organs, and heart failure as a result of amyloid disease has been described. However, there is no known background for the development of amyloid disease, and the blood and urinary findings do not suggest amyloid nephrosis.

The electrocardiographic findings are of more than passing interest; it would be helpful to know whether there was any abnormal axis deviation.

DR. PAUL D. WHITE: The abnormality consisted of bundle-branch block, with left-axis deviation and low voltage of the QRS waves.

DR. GRAYBIEL: In the presence of bundle-branch block, axis deviation cannot safely be relied on for the determination of ventricular preponderance. The very long QT interval deserves comment. It may be quite long in heart block—as long as 0.5 second. It is abnormally long in hypocalcemia, in certain types of severe heart disease with marked dilatation of the heart, and in other pathologic states. Complete auriculoventricular block in any type of heart disease is relatively uncommon: a few years ago, we had observed only 72 cases in this hospital. It is of interest that 4 of these 72 were undoubtedly of congenital origin, and this was the likely etiology in 2 others (over 8 per cent). One of the 6 cases of complete heart block of congenital origin was in an infant whose twin brother had high-grade heart block with a slow ventricular rate. In the case under discussion, the possibility of congenital heart block must be strongly considered; it is very unusual to have complete auriculoventricular block in two young

siblings on the basis of any type of heart disease other than congenital.

May we see the x-ray films?

DR. JAMES R. LINGLEY: We do not have the previous x-ray films for comparison. These films show gross enlargement of the heart, the enlargement being general but most marked in the region of the left ventricle. There is also distinct prominence in the region of the left auricle. This shadow in the right cardiophrenic angle interests me very much because we have seen right-sided diaphragmatic hernias that looked like that. There may be herniation of the transverse colon through the right side of the diaphragm, or a herniation of the omentum. A barium enema was advised, but evidently the patient was too ill to have that examination. It could have been a pericardial cyst or a localized encapsulation of fluid, but both possibilities are unlikely.

DR. GRAYBIEL: Do you think that there was pericardial effusion?

DR. LINGLEY: I do not believe that there was any pericardial fluid.

DR. GRAYBIEL: The coughing spells shortly before death—which raised blood-streaked sputum and were associated with pain and tenderness in the calf—raise the question of pulmonary emboli. It is even conceivable that the illness began with an embolus that lodged in the pulmonary artery and caused preponderant right-sided heart strain and congestive failure; such cases have been described.

Finally, the terminal event may have been due to the breaking away of a mural thrombus from the left ventricle, with embolism to the brain, or death may have resulted simply from the severe degree of congestive failure.

We have, then, the unusual story of a young man who, within six months, developed heart failure and died. This story becomes the more remarkable when it is learned that a sister died of a similar illness and that both had complete auriculoventricular block. The degree and extent of the edema suggests either a severe grade of predominantly right-sided heart failure or some mechanical obstruction on this side.

It seems to me that a diffuse myocardial process must be considered as the possible cause of the signs and symptoms described. A number of cases of myocarditis of essentially unknown origin have been observed. "Isolated myocarditis" and "interstitial myocarditis" are terms sometimes used.

There is no good evidence that the heart disease was of rheumatic origin: there was no fever or joint pains, and murmurs were not heard until the terminal stages. Fiedler's myocarditis might

be mentioned, but fever is a characteristic of this disease. Syphilitic myocarditis is unlikely, not only because of its rarity but because the blood Wassermann reaction was negative. An endocrine hepatocardiac syndrome characterized by cirrhosis of the liver, pigmentation and infantile regression and followed by severe heart failure has been described. However, most of the characteristics of this syndrome were not present. Von Gierke's (glycogen-storage) disease must be mentioned. But this diagnosis seems unlikely when it is recalled that the patient was able to work as a truck driver until six months before admission to the hospital. Pericarditis with effusion is a possibility, and even the appearance of the heart in the x-ray film is not inconsistent with a considerable amount of fluid in the pericardium.

Nevertheless, I am led back to the original idea that in this case there was a myocarditis of essentially unknown origin that produced an extreme degree of cardiac enlargement, and that there may have been a mural thrombus, a portion of which broke away to cause cerebral embolism and death.

DR. WHITE: I came in contact with this case, having had correspondence with the patient's physician in another city, who spoke about the mystery of the illness and asked if we could take the patient for study. Although he lived only four days after arrival, we were able to make a satisfactory study; and he had been in the other hospital long enough to have even more complete studies.

Dr. Frank N. Wilson, of Ann Arbor, Michigan, was asked for an opinion. He wrote:

The story that you give in your letter is very peculiar and interesting. Complete heart block in young people is unusual. It is seen in congenital heart disease occasionally but almost always, if not always, in association with a defect in the ventricular septum and consequently with a systolic murmur that is loudest in the central part of the precordium. I have recently seen one case in which heart block may possibly have been due to myxedema, and it might be worth while to try the effect of desiccated thyroid. Syphilis of the myocardium, without definite evidence of involvement of the aorta, is extremely uncommon but does occur. It would be extremely unlikely in a man of twenty-one. Vitamin B<sub>1</sub> deficiency is said to cause very striking changes in the heart at times, but I do not believe that heart block has been reported. A severe deficiency of this type, with edema, is common, but there are neurologic changes. I take it that there is nothing in the history to suggest a deficiency disease. Marked enlargement of the heart may occur in sickle-cell anemia, which of course is, practically speaking, confined to Negroes, and in pituitary disease, particularly acromegaly. There does not seem to be any suggestion of this last condition here.

There is also a letter from Dr. Robert S. Starr, of Hartford, Connecticut, who had seen the patient. His final opinion was as follows:

It is doubtful whether congenital heart disease of any type could have been present throughout this boy's life without causing some degree of incapacity previous to the present illness. Moreover, the absence of murmurs and other objective evidence of congenital heart disease makes this diagnosis unlikely. Electrocardiograms, however, seem to indicate that the interventricular septum is rather particularly involved in the disease. The remarkable size of the heart by x-ray examination and the somewhat definite left ventricular and left auricular enlargement are noteworthy, but the symptoms so far have been chiefly those of failure of the right heart. Von Gierke's disease, although it must be considered, seems doubtful in the absence of a large liver.

I can add nothing except the note that I made on the ward the second day after admission.

Marked cardiac enlargement—dilatation and hypertrophy—with failure and extensive involvement of the auriculoventricular conduction system (complete heart block and left bundle branch block). A very bizarre syndrome at this age not fitting in with any ordinary cardiac diagnosis (rheumatic, congenital coronary or diphtheritic). It is possible, from the family history, x-ray findings and absence of other etiology, that rare neoplastic disease or von Gierke's (glycogen storage) disease may be responsible. It is not likely that we shall be able to establish an ante mortem (or perhaps even a post mortem) diagnosis.

#### CLINICAL DIAGNOSES

Congestive heart failure  
Von Gierke's disease

#### DR GRAYBIEL'S DIAGNOSES

Myocarditis, of unknown origin  
Complete auriculoventricular block, of congenital origin  
Cardiac enlargement, marked  
Congestive failure, marked  
Mural thrombi and cerebral embolism?  
Pericarditis, with effusion?  
Pulmonary embolism?

#### ANATOMICAL DIAGNOSES

Idiopathic hypertrophy and dilatation of the heart  
Mural thrombus, right auricle  
Pulmonary infarcts, multiple  
Anasarca  
Chronic passive congestion  
Thrombosis of posterior tibial veins

#### PATHOLOGICAL DISCUSSION

DR THOMAS B. MALLORY. Dr White's last statement is perfectly true. This man had an enormously dilated, moderately hypertrophied heart, one of the largest hearts from the point of view of capacity that we have ever seen, and all the chambers shared in the dilatation and in some degree of hypertrophy. The actual weight was

600 gm. The tricuspid valve measured 17 cm in circumference, the mitral between 13 and 14 cm. They are the two largest valve rings we have ever seen. The aortic and pulmonary valve rings, however, were quite normal. The coronary arteries were entirely normal. We made many microscopic sections of different areas of the myocardium, and none of them showed abnormality. The muscle fibers were somewhat larger than normal, but they showed no vacuoles of either glycogen or fat. There was not the slightest trace of inflammatory reaction to suggest myocarditis. The epicardium showed numerous petechial hemorrhages, which were found in various other spots in the body. It was noted that the blood had not clotted post mortem. Such failure of post-mortem clotting is suggestive evidence of an asphyxial death. There was a thrombus in the left auricular appendage, which could have been the source of five pulmonary infarcts that were found. On the other hand, the patient also had thrombosis of both posterior tibial veins, and I think that is the more probable source. Although there were several emboli, they had not produced large areas of infarction, and none of them were of sufficient size so that one could attribute death to pulmonary embolism. We made glycogen stains of various other organs, as well as of the heart, to be perfectly sure that we were not dealing with von Gierke's disease, and no abnormal deposits were found. The kidneys showed nothing that could not be explained by passive congestion.

DR DONALD S. KING. How about the shadow on the right side of the heart?

DR MALLORY. Perhaps that was one of the pulmonary infarcts.

DR WHITE. Each year, at the time of our graduate courses, we try to present one such case as this. It is not only very humbling, but it is also stimulating for our own further studies.

DR MALLORY. A year ago, an almost identical case<sup>1</sup> was presented, in older man, forty years of age, with marked hypertrophy and dilatation of the heart and absolutely nothing to explain the condition. Such cases have been reported in small numbers. Levy and Rousselot<sup>2</sup> reported 3 cases clinically similar, but 2 of these cases showed degenerative changes in the ventricular muscle.

A PHYSICIAN. There was no pulmonary endarteritis?

DR MALLORY. No.

## PROCUREMENT AND ASSIGNMENT SERVICE

AN urgent call to all physicians to enter military service in the present emergency appeared in the January 1 issue of the *Journal*, as well as in the December 27 and January 3 issues of the *Journal of the American Medical Association*. The following statement by the Procurement and Assignment Service concerns the response of the medical profession and contains additional information that is of interest to those who, for one reason or another, cannot enlist in the United States Army or Navy:

The response of the physicians of the country to the Procurement and Assignment Service request for enrollment of those now ready for immediate service in the United States Army or Navy is highly gratifying. All names are being processed and those who meet the present demands of the Surgeons General will receive application forms and authority to appear for physical examination at an early date. All who are now ready for immediate duty should forward applications to the Procurement and Assignment Service at once. It is not the intention of the Procurement and Assignment Service to register every physician, dentist and veterinarian at the present time. Only those available for immediate assignments should register at this time. The physical requirements of all military, governmental, industrial, and civil agencies will be published in national and state journals immediately. On the basis of this information every physician, dentist and veterinarian will be able to make a self-appraisal of his physical qualifications. Within a few weeks the Procurement and Assignment Service will mail to all applicants a form on which they will be asked to state their preferences for assignment to all agencies of national defense which require medical, dental and veterinary personnel and for service in communities in public health and other civil categories. In this way every physician, dentist and veterinarian of the country will be able to lend maximum support to the national emergency. In order to meet the expanding needs of the military services, every physician immediately available for duty should mail his application blank to the Procurement and Assignment Service at once. All others will be given an opportunity to volunteer in the near future.

## UNITED WAR FUND CAMPAIGN

THE Greater Boston United War Fund Campaign, which begins on January 22 and will continue until February 11, represents a concerted endeavor on the part of the Greater Boston Community Fund, the American Red Cross, the United Service Organizations and the local Soldiers and Sailors Committee to raise \$7,600,000—nearly \$3,000,000 more than the goal of the Community

Fund last year. Boston is the only community of comparable size in which such a joint campaign is being conducted. Success therefore becomes a matter of civic pride and an example to other cities.

The campaign epitomizes the war effort of the Nation—the answer of free men to the threats of slaves and tyrants. For the money contributed, which will eventually have the effect of supporting the men in battle, is given voluntarily by those who wish to affirm their belief in the worth of liberty and justice. The American Red Cross sustains the morale of the armed forces in the field, distant outposts and hospitals by providing a link of communication between these men and their families; in addition, it must provide shelter, food, clothing and medical aid to the civilian victims of bombing, sabotage and other disasters. The United Service Organizations and the Soldiers and Sailors Committee direct their activities toward maintaining the morale of the service men. The Community Fund guards the vital home front: it protects the general population against poverty, sickness and despair—a trilogy that is potentially more menacing than armed invasion.

The war is on. Already, Pearl Harbor and Manila have become names to be remembered, names that mean temporary and honorable retreat before a treacherous, and therefore unexpected, assault. If the men who gave their lives in those battles are to be vindicated, every effort against the enemy must be supported. And the United War Fund Campaign represents such an effort.

The enormous goal can be attained only through the generosity of those who contribute. And this means sacrifice at a time when the burden of unprecedented taxation is becoming a reality. The quota of the Physicians' Group, \$37,415, is an increase of nearly 100 per cent over the total raised in last year's campaign. Physicians, accordingly, may well wonder how they can be expected to give such a sum: the number who are able to give contributions of several hundred dollars is decreasing; the doctor, like everyone

else, faces a discouraging rise in his tax rate; and many medical officers have already begun duty with the Army and Navy. The only solution is for *all* physicians to give. Those who have given before must be even more generous, and those who have not supported previous campaigns must contribute in proportion to what they have.

The United War Fund Campaign should be considered a call to arms for those who are being protected, after all, from the full shock of enemy attack. Moreover, the campaign is a challenge to all who prize their liberty sufficiently to fight for it. It is to be expected that physicians will be among the first to meet such a challenge.

## MEDICAL EPONYM

### MALPIGHIAN CORPUSCLES

"De internis glandulis renalibus, earum continuatione cum vasis [The Internal Glands of the Kidneys and Their Connection with the Blood Vessels]" is the title of the section of the discussion of the kidneys in which Marcello Malpighi (1628–1694), primarius in the Academy of Medicine at Messina, describes these structures. The quotation is taken from the edition of his *De viscerum structura exercitatio anatomica* [*Anatomical Essay on the Structure of the Viscera*], published at London in 1669, the first edition having been published at Bonn in 1666. A portion of the translation follows:

Since we have shown in a previous section that glands are found in the kidneys, and since, as will be shown below, these perform a special function in the excretion of the urine, it is advisable to spend a little time on them. They are located in the outermost part of the kidneys, are almost infinite in number, and probably correspond to the urinary vessels, which join to make up the main bulk of the kidneys. They are gathered into separate bundles, more than forty in number, and it is by virtue of these that those small divisions arise which appear in all kidneys. Wherefore, no definite description of their shape can be given on account of their minuteness and transparency, which is their chief characteristic: they seem, however, to be round like fish eggs, and while a black humor is passing through the arteries, they turn black; one might say that all round them they have shoots, moving like twining tendrils, so that they appear to be wreathed around, so to speak—with this exception, however, that the main part, which is fastened to the branch of the artery, turns black, whereas the rest retains its own color.

## COMMITTEE ON MATERNAL WELFARE

ANALYSIS OF CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1940 (*continued*)

## EMBOLISM

The immediate cause of death in 28 cases was embolism. Table 1 presents an analysis of these cases.

*After normal delivery.* A cerebral embolus occurred in 1 patient who was suffering from pulmonary tuberculosis. It was stated that she had only a short time to live in any event, and that the pregnancy had simply shortened her life. Three patients died after they had left the hospital—2 within twenty-four hours and 1 ten days later. It

TABLE 1. *Deaths due to Embolism.*

OCCURRENCE OF EMBOLUS	NO. OF DEATHS
After normal delivery	11
After operative delivery	7
After cesarean section	5
After abortion	2
During pernicious vomiting	1
During labor	1
After a separated placenta	1

is interesting that no serious pelvic operation preceded these embolic deaths. In 1 case, the patient delivered herself at about seven months; a few days after delivery, she was operated on for acute appendicitis and intestinal obstruction, and subsequently for a postoperative abscess. This patient died very suddenly just as she was leaving for home. The pregnancy may have obscured the diagnosis of appendicitis, because it was not definitely recognized until after delivery, although there had been symptoms preceding labor; this was a surgical death, but the immediate cause was embolism.

*After operative delivery.* In the 7 operative cases, 1 patient was delivered by version. She ran a febrile convalescence, and it is quite likely that an incomplete rupture of the uterus was sustained at the time of the delivery. One death occurred abruptly seven hours after delivery, and was undoubtedly due to embolism. One patient who was delivered by a low-forceps operation died the day after she arrived home; it was said that her convalescence had been entirely normal while she was in the hospital. Another patient developed an embolus three days after leaving the hospital and died abruptly. Another died on the ninth day, when she got out of bed. In 1 case, in which a low-forceps delivery was performed, the patient had an embolus about twenty minutes after de-

livery, and died four hours afterward. One patient, who developed respiratory embarrassment at the beginning of anesthesia, never recovered. Of course, it cannot be ruled out that the anesthetic was not the cause of this death, but the history suggests embolism. One patient delivered by low forceps developed respiratory embarrassment after 9 gr. of Nembutal and 1/150 gr. of scopolamine. The cyanosis was associated with much mucus and no vomiting; no anesthetic was given. This death was ascribed to embolism, although barbiturates may have really been responsible. The doses in this particular case were 3 gr. of Nembutal at 2:00 a.m. and 4 gr. at 6:00 a.m., with 1/150 gr. of scopolamine. About the only medical criticism in the treatment of these cases is that in the patients who left the hospital and died a few days after reaching home, phlebitis probably existed in each case and had not been diagnosed.

*After cesarean section.* There were 5 fatal cases of undoubted pulmonary embolism following cesarean section: 1 on the sixth day; 1 on the tenth day; 1 on the fifth day; 1 in a patient who was about to leave the hospital; and 1 four weeks following the operation as the patient was about to be discharged. The last patient had had an initial embolus at ten days. The number of deaths from embolism after cesarean section emphasizes the fact that fatal emboli are much commoner in cesarean sections than in normal deliveries. Embolism has always been recognized as a hazard of abdominal surgery, and because of this hazard, cesarean sections should never be entertained lightly.

*After abortion.* Miscarriage occurred in a patient one day after she had been operated on for acute appendicitis. Apparently, she was convalescing normally when suddenly, nine days later she went into a state of shock and died. One case of self-induced abortion was definitely septic. After she reached the hospital, this patient had been treated in the most approved manner—with transfusion, blood culture, no interference with the uterus and sulfanilamide therapy. Undoubtedly the embolus that caused her sudden death came from a thrombus in the pelvic veins. This case was turned over to a medical examiner, but no autopsy was performed.

*During pernicious vomiting.* In the case of pernicious vomiting, the patient died without operative interference. No attempt was made to interrupt the pregnancy, and it is probable that intravenous therapy had something to do with this death because the distress began three hours after intravenous glucose medication, and death occurred three minutes later. But, since this woman

was pregnant, the death was classified as a maternal death.

*During labor.* In a case of abnormal presentation, the patient died during labor. She was treated conservatively until full dilatation, and while being prepared for anesthesia, developed a severe pain in the chest and died within two minutes. In no way can the handling of this case be criticized. Unfortunately, an autopsy was not performed.

*After a separated placenta.* In the case of separated placenta, the patient was treated conservatively by cervical packing and an abdominal binder; although she had an anuria, which cleared up so that she passed 1200 cc. of urine on the ninth day, that evening she developed acute pain, cough and bloody sputum, and died eight hours later. One does not know how to prevent such a catastrophe.

\* \* \*

On the whole, a review of these deaths from embolism shows that most of them, in the present state of knowledge, are unavoidable. Patients who had been running slight fevers and died as they were about to leave the hospital, or a few days after they had returned to their homes, were not treated so conservatively as present knowledge teaches. It is possible that some of these cases might have been prevented had a diagnosis of phlebitis been made and had the vein at fault been operated on. This is a new branch of surgery, and at present only those who have had large experience in vein surgery should pass on each individual case. It has been suggested that heparin be used on operative deliveries when the element of trauma has been excessive. Since most of the cases of embolism were not associated with operative procedures, it seems as though the incidence following such procedure was not so great as it had been thought, and the cost of heparin therapy is still so prohibitive that any extensive research in the prevention of phlebitis and subsequent embolism by its use is out of the question.

## DEATHS

**BYRNES**—JOHN P. BYRNES, M.D., of Springfield, died recently. He was in his fifty-first year.

Dr. Byrnes received his degree from Albany Medical College in 1914. He was a former member of the Massachusetts Medical Society.

**HERSAM**—NORMAN P. HERSAM, M.D., of Stonham, died January 15. He was in his fifty-eighth year.

Dr. Hersam received his degree from Harvard Medical

School in 1912. He was a fellow of the Massachusetts Medical Society and the American Medical Association. His widow survives him.

## WAR ACTIVITIES

### EVACUATION SYSTEM MANUAL NO. 2

#### MEDICAL ORGANIZATION FOR PLAN A—EMERGENCY DISASTER

THIS IS THE SECOND MANUAL TO BE PUBLISHED RELATING TO CIVILIAN EVACUATION. ITS PURPOSE IS TO AID LOCAL SAFETY COMMITTEES IN ESTABLISHING ADEQUATE MEDICAL SERVICES IN CONNECTION WITH EVACUATION.

THE EVENT WHICH WILL MAKE AN EVACUATION OF THE CIVILIAN POPULATION NECESSARY WILL BE AN EVENT OF VIOLENCE. ITS INEVITABLE EFFECT UPON THE HUMAN BEINGS INVOLVED WILL BE THE DISRUPTION OF THEIR NORMAL CONDITION, BOTH PHYSICALLY AND MENTALLY: THE SHOCK, THE GRIEF, THE LOSS AND THE EXPOSURE WILL CREATE MANY MEDICAL PROBLEMS. THESE PROBLEMS MUST BE MET EFFICIENTLY AND PROMPTLY NOT ONLY FOR HUMANITARIAN REASONS BUT ALSO FOR REDUCING TO THE MINIMUM THE LOSS WHICH THE ENEMY SEEKS TO INFLICT.

J. H. SHERBURNE, *Director*  
Evacuation Division

Massachusetts Committee on Public Safety

Two previous publications dealing with civil evacuation have been issued by the Massachusetts Committee on Public Safety. *Bulletin No. 1: Evacuation of Civilians* considered the problem inherent in evacuation and gave information to be used in making evacuation plans. *Manual of Evacuation System, No. 1: Organization Plan A—Emergency Disaster* defined plans of evacuation to meet different types of emergency, described the organization to be developed and discussed the operation of these plans. The present manual is intended to describe the medical aspects of evacuation and the duties of evacuation medical officers. All evacuation medical officers should be thoroughly conversant with the previous publications.

*Bulletin No. 1: Evacuation of Civilians* was concerned with the removal of certain priority groups from danger zones to places of relative safety. Since its publication in June, 1941, the duties of the Evacuation Division have been broadened to include the evacuation and emergency care of all groups, except casualties, in the civilian population in the event of bombing or other war disasters. Obviously this is disaster relief, which is one of the major activities of the American Red Cross. It is therefore of the utmost importance that there exist the greatest co-operation between officers of the Medical Division, the Evacuation Division and the Red Cross, in order that there may be full utilization of all available resources. Red Cross facilities are to be augmented, not supplanted. It has been agreed between the Red Cross and the Evacuation Division that the former will supply, in so far as possible, ambulance service, mobile canteens, food, clothing, bedding, supplies and temporary shelter. Nursing care may also be provided, principally in the form of nurses aides. Medical personnel is furnished by the Evacuation Division.

*Manual of Evacuation System, No. 1: Organization Plan A—Emergency Disaster* defines five different types of evacuation. Plan A, the first to be worked out in detail, provides for the care and resettlement of civilians following an emergency disaster. Plans B, C, D and E probably

would be less hurried in their execution and would provide for resettlement on a long-term basis.

Civil evacuation will be voluntary except when compulsory evacuation is executed at the order of the military authorities or the government. The expense of evacuation will be met from public funds, but individuals cared for away from home will be expected to reimburse the government whenever possible for the cost of such care, either in whole or in part.

The specific objects of this Manual are as follows: to describe the duties of evacuation medical officers in the execution of Plan A; to describe the equipment and personnel needed; and to describe the various registration and examination forms and to discuss their use. Other manuals will be issued later in relation to Plans B, C, D and E.

#### ORGANIZATION AND DUTIES OF EVACUATION MEDICAL PERSONNEL

The organization of the Evacuation Division was described in *Manual of Evacuation System, No. 1: Organization Plan A—Emergency Disaster*. Its director will be assisted by a group of staff officers, among whom will be the chief evacuation medical officer and his deputy. It will be their duty to simplify, standardize and integrate all the medical activities of the Evacuation Division. They will be responsible for determining policies, outlining general plans and allocating evacuation medical facilities within the Commonwealth. They will send information to the regional evacuation medical officers and, through them, to the local communities. They will also maintain contact with the other divisions of the Committee on Public Safety, with the Red Cross, and with the Office of Civilian Defense for co-operative action between the states. They will have such advisory and liaison officers as are necessary.

Working under the state officers will be nine regional evacuation medical officers and their deputies. These officers will be called to duty at their regional headquarters in the event of an emergency. They will assist in every way the work of local evacuation medical officers. They should participate in the development of local evacuation facilities and arouse public interest in the work of the Evacuation Division. They control, through their district officers, all communications dealing with the medical aspects of evacuation between cities and towns in their regions. Communities needing additional medical assistance for evacuation should communicate with the regional evacuation medical officer and not with officers in adjoining localities. These might be equally affected by the disaster.

For each local evacuation officer, there will be appointed an evacuation medical officer and deputy, who will supervise the physicians, nurses and other personnel in their city or town who are working under the Evacuation Division.

An evacuation medical officer will be assigned to each report(control)-center area. He is the chief evacuation medical officer for that area, although there may be other evacuation medical officers working with him. One report center is usually organized for each 50,000 people in the State. It is the focal point from which all emergency service is rendered, and is controlled by the chief air-raid warden. Every evacuation medical officer should be thoroughly familiar with *Medical Handbook No. 2*, and also with the A.R.P. System. He should acquaint himself with all local facilities, especially those of the Red Cross, and should understand their organization. He should show the utmost co-operation in the use of these

facilities. He should know that supplies and equipment exist in fact as well as on paper. Personnel should be listed by address and telephone number, and should be fully acquainted with their duties. When the Red Cross or other agencies are not able to furnish nursing personnel, it shall be his responsibility to obtain nurses from other sources.

#### 1. Assembly Stations

Assembly stations will be selected in each community, their number and location depending on local conditions. They may be situated in buildings taken over for medical depots or may be identical in location with the casualty stations of the Medical Division. These assembly stations are under the direction of the Evacuation Division. The evacuation officer at the station will need the services of a physician, who will be provided by the Medical Division from their personnel present at the medical depot. He will be assigned to this duty by the chief medical officer at the report center. The medical officers of the Evacuation Division will not as a rule be called to duty until the temporary shelters have been selected. The chief evacuation medical officer should be sure that this arrangement is clearly understood.

It shall be the duty of the medical officer at an assembly station to reassure and calm any excited, worried or hysterical individuals—morale is of major importance and a competent individual can do much to keep it high—and to inspect all evacuees and treat any minor injuries or medical conditions that may be found.

In Appendix A will be found a list of the equipment needed at an assembly station. Arrangements have been made with the Medical Division to supply this kit and keep it filled. The chief evacuation medical officer is responsible for seeing that this equipment is kept at the medical depot and that supplies are replenished as necessary.

Any group of evacuees may include individuals subject to heart attacks, epileptic seizures and other medical emergencies, such as labor induced by the excitement of the occasion. To avoid confusion and therapeutic mistakes, each person receiving medical treatment will have this noted on an identification tag (the one used by the Medical Division), which should be attached to his person. In addition, a record must be kept of all medical treatment in a book provided for each unit. This must be returned daily to the chief medical officer at the report center at the end of each tour of duty.

#### 2. Transport

The medical officer at the assembly station will usually have no duties in connection with the transport of evacuees to temporary shelters, unless an urgent medical situation arises. The distances to temporary shelters will be short.

#### 3. Temporary Shelters

The medical officers of the Evacuation Division are responsible for medical care at the temporary shelters. As soon as the location of a temporary shelter has been selected, the chief evacuation officer will notify the chief evacuation medical officer who should at once go to the medical depot, collect his equipment and proceed to the temporary shelter. This chief evacuation medical officer will also call to duty sufficient nursing personnel. He will be responsible for the medical care of evacuees until the temporary shelter is cleared. Provision must be made for relief personnel, if necessary.

At the temporary shelter, considerable medical care

may be needed. The required equipment (Appendix B) will be supplied by the Medical Division. The chief evacuation medical officer is responsible for seeing that this equipment is on hand and kept in an appropriately labeled container at the medical depot. The evacuation medical officer will be responsible for having this kit brought to the temporary shelter when he goes on duty.

The medical personnel supplied to a shelter will vary according to the number of evacuees. There should, if possible, be at least one nurse for every one hundred evacuees, and aides should be supplied in the same ratio. Volunteers may be used for clerical help. All the facilities of the Red Cross will be needed, and should be used to the fullest extent.

All medical treatment must be recorded. If an identification tag was attached to the evacuee at the assembly station, the treatment should be noted on this tag, or if the evacuee is untagged, a tag should be attached and the entry should be made thereon. If, however, the evacuee has been registered, the entry can be made directly on the evacuation registration card (see below). All identification tags should eventually be removed and filed, and any entries made thereon should be copied on the evacuation registration card. A record of treatment must also be kept in the book provided with the medical kit.

Registration of evacuees by card will be done for administrative purposes and does not directly concern the medical officer. However, inasmuch as some persons will require emergency treatment, and since, under certain conditions, mass immunization may be necessary, space will be provided on these evacuation registration cards for medical information.

The chief evacuation medical officer or his deputy should be available to advise and consult with evacuation officers at information centers (see *Manual of Evacuation System, No. 1*) in the disposition of evacuees with medical or medicosocial problems. He should have a thorough knowledge of the Evacuation System, and should be conversant with the medical difficulties likely to be encountered in caring for children and persons handicapped by age or illness.

#### 4 Resettlement

Most of the evacuees will find permanent quarters for themselves and will need no medical examination other than the cursory inspection given at the assembly stations and temporary shelters. Those who have received some medical treatment should be given instructions concerning continuation of medical supervision, if necessary. There should be consultation with the Medical Division regarding facilities. A small percentage of the evacuees will require billing by the Evacuation Division. These persons will have a medical registration card and will receive a medical examination. So far as possible, evacuees will be housed in the locality, but they may be moved into another community, another region or, in the event of a major disaster, into another state. The chief evacuation medical officer at the place receiving them, wherever it may be, will act in accordance with procedures for a reception area, which will be considered in another manual.

For the medical registration of evacuees, cards of varying colors will be used, to permit rapid sorting by priority groups. The system will be as follows:

*White*—Healthy persons over fifteen years of age

*Blue*—Healthy children five to fifteen years of age

*Green*—Healthy children under five years of age

*Red*—Expectant mothers

*Orange*—Cripples, the aged and infirm, and handicapped individuals regardless of age

The term *healthy* is to be liberally interpreted. It should include individuals having slight handicaps, such as mild cardiac disease, malnutrition and other defects not limiting normal activities to any significant degree.

Such a system of classification will expedite the sorting of evacuees and aid in determining to what extent special medical facilities will be required. For example, plans will have to be made for the care of the aged in special homes, for the delivery of pregnant women in maternity hospitals and for the care and treatment of persons with such handicaps as blindness, crippling mental deficiency and convulsive disorders.

*Medical examination.* The medical registration card, which will go with the evacuee to the area in which he is resettled, should include a record of medical examination, which will be the beginning of a cumulative medical record.

Detailed and inclusive physical examinations do not seem necessary or feasible in view of the complexities and confusion of any evacuation and the possible shortage of medical personnel. The examination should be considered a rough screening process designed to eliminate individuals with contagious disease or serious handicaps. In children, the conditions most likely to be encountered are the exanthems, impetigo, pediculosis, scabies and, in young girls, vulvovaginitis. Adults should be inspected for the exanthems even though the probability of their contracting them would not be great. Examination for tuberculosis, syphilis and gonorrhea does not seem practical under these conditions.

Part of the medical inspection can be done by a nurse, leaving the physician to devote his time to the more important phases of the examination (about five minutes should be allowed) and to make final judgment in doubtful cases. Individuals over fifteen years of age should have a brief examination of the lungs and heart. Volunteer workers may be used for clerical assistance.

Evacuees who show signs of acute illness sufficient to make bed care necessary or who have developed any of the exanthems must be hospitalized. Arrangements for hospital and isolation facilities will require the co-operation of the Medical Division. If serious conditions are encountered, individuals should be sent by ambulance to the nearest hospital. Minor contagious conditions, such as impetigo, scabies and pediculosis, should not prevent the transportation of affected evacuees. If such individuals are to travel long distances in large groups, they should be segregated during their travels, and treatment should be begun as soon as they reach the reception area. In addition to the medical registration card, which will go with the evacuee to his final destination and there be kept in the custody of the chief evacuation medical officer, a travel tag indicating the evacuee's medical status, will be provided. This will facilitate the handling of mildly contagious evacuees. It will be attached to his person after he has undergone his medical examination.

*Transportation.* The transportation of evacuees will not be difficult when they are resettled locally. Except for the sick and the handicapped or for those in large urban centers many of them will be able to walk to their destination. However, evacuees may have to be moved in large groups and for a considerable distance, in which case more detailed plans will be necessary. Under these circumstances, as soon as evacuees have been registered and have passed the medical examination, they will be grouped and assigned to whatever buses, automobiles or trains may have been reserved for them. The evacuation officer in charge of each party shall be responsible for the

medical registration cards during transport, and shall deliver them to the chief evacuation medical officer at the resettlement area.

Healthy adult refugees will not need any more supervision in transit than would be provided by the transport officer in charge of the party, except when they travel in large groups. Healthy children from five to fifteen years of age will be adequately supervised by their school teachers or other individuals to whom this duty is delegated. More care will be required for young children, and medical supervision will usually be reserved for them and for handicapped evacuees. Special arrangements for such groups will be made by the local evacuation officer after consultation with his evacuation medical officer, his transport officer and any other interested parties.

It is assumed that each trainload or convoy of evacuees will at least be accompanied by persons who have had adequate Red Cross training and who have first-aid supplies to deal with minor emergencies.

If evacuees are transported distances requiring a traveling time of several hours, it is to be anticipated that medical emergencies will occasionally arise. Certain towns should be designated along the route where patients may be left in the hands of the local evacuation officer. If possible, he should be warned by telephone or telegram of his approaching responsibility, so that he may have time to make arrangements before the evacuee arrives.

If evacuees travel by auto or bus, they will probably arrive at the resettlement area directly. If, however, they go by rail, intermediate steps may be necessary before final billeting. Local evacuation medical officers must therefore arrange for certain medical facilities at disembarkation points. They and their aides should have armbands, uniforms or other distinguishing insignia. Equipment such as that described for assembly stations should be on hand.

This bulletin will not deal with the medical problems to be encountered in resettlement areas. It is obvious that long-term medical care of evacuees will require special planning. There will be time for epidemics of communicable disease to occur, and some control system must be set up. It may be necessary to arrange for clinic, hospital and domiciliary care of evacuees. The mental effects of bombing, separated families and strange surroundings will create new, and often disturbing, problems, especially among children. This phase of the evacuation process will be discussed in a later manual.

#### APPENDIX A. *First-Aid Equipment for an Assembly Station.*

- 6 pkg. Bandage compress, 3 in., 2 per pkg.
- 2 pkg. Tannic acid jelly
- 2 pkg. Gauze, absorbent, 1 yd. per pkg.
- 2 Bandages, gauze, 3 in.
- 4 Bandages, cravat triangle
- 48 Tags, identification
- 1 bot. Aromatic spirits of ammonia, 120 cc.
- 1 bot. Morphine sulfate, sterile solution, 20 cc., with rubber-diaphragm stopper (1 cc. contains  $\frac{1}{4}$  gr. morphine sulfate)
- 1 Syringe, Luer, 2 cc.
- 12 Needles, hypodermic, 24 gauge
- 1 bot. Alcohol, 90 per cent, 120 cc.
- 1 pkg. Nitroglycerin tablets, 100 per pkg.
- 1 pr. Scissors
- 1 pr. Tweezers
- 1 Pencil, indelible

- 1 Flashlight
- 1 box Throat sticks, 10 per box
- 1 Stethoscope
- 1 pkg. Drinking cups, paper
- 1 Book, record

These articles should be packed in a durable, clearly labeled container such as a haversack or suitcase.

#### APPENDIX B. *Medical Equipment for a Temporary Shelter.*

- 6 pkg. Bandage compress, 3 in., 2 per pkg.
- 2 pkg. Tannic acid jelly
- 2 pkg. Gauze, absorbent, 1 yd. per pkg.
- 2 Bandages, gauze, 3 in.
- 1 Gauze kit, Red Cross
- 4 Bandages, cravat triangle
- 1 lb. Cotton, absorbent
- 1 bot. Aromatic spirits of ammonia, 120 cc.
- 1 bot. Morphine sulfate, sterile solution, 20 cc., with rubber-diaphragm stopper (1 cc. contains  $\frac{1}{4}$  gr. morphine sulfate)
- 1 Syringe, Luer, 2 cc.
- 12 Needles, hypodermic, 24 gauge
- 1 bot. Alcohol, 90 per cent, 180 cc.
- 1 pkg. Nitroglycerin tablets, 100 per pkg.
- 1 pkg. Pentobarbital capsules,  $1\frac{1}{2}$  gr., 100 per pkg.
- 1 tube Vaseline, sterile, 45 cc.
- 1 pkg. Aspirin tablets, 5 gr., 100 per pkg.
- 1 bot. Suprarenalin solution (1:1000), 30 cc.
- 1 Catheter, urethral, rubber, No. 14 Fr.
- 1 Stethoscope
- 1 Flashlight
- 48 Tags, identification
- 1 pr. Scissors
- 1 pr. Tweezers
- 1 Pencil, indelible
- 2 boxes Throat sticks, 10 per box
- 1 box Safety pins
- 1 pkg. Drinking cups, paper
- 1 Book, record

These articles should be packed in a durable, clearly labeled container such as a suitcase or wooden box.

## MISCELLANY

### AMERICAN TRUDEAU SOCIETY

The diagnosis of clinically significant pulmonary tuberculosis is readily reached by the average practicing physician if certain fundamental procedures are used. One of the functions of the American Trudeau Society, the medical section of the National Tuberculosis Association, is to disseminate, among the general medical public, information about advances in these procedures. The treatment of tuberculosis in general is a specialized procedure, which should at least be initiated with the counsel of a specialist. The American Trudeau Society offers a forum where practitioner and specialist can meet to discuss the technical problems involved, as well as their practical application, and the following remarks of its president, Dr. Harold G. Trimble, are of interest.

\* \* \*

The American Trudeau Society is a natural outgrowth of the American Sanatorium Association, which was formed in the days when most of the medical problems of tuberculosis revolved around the various tuberculosis institutions and when many of the men in tuberculosis work

came by their interest because of their own personal history as tuberculosis patients. With increasing diagnostic facilities and with advances in various forms of treatment, general medical interest in diseases of the chest, including tuberculosis, was significantly increased and many young physicians became interested in these problems as such.

Theoretically, it seemed profitable, and practically it so developed, that contact between what one may call the pure specialist in tuberculosis and the internist, who although having other interests was intimately concerned with diseases of the chest, would benefit both. On this basis then with the co-operation of the National Tuberculosis Association the American Trudeau Society was formed—an organization of medical men with a nucleus of those interested primarily in tuberculosis and including a group interested in general internal medicine.

The idea of such a society, which would be inclusive rather than exclusive,—that is not confined to men who were primarily specialists in diseases of the chest—caught hold among the medical public, as evidenced by the rapid increase in members. Such an organization has a dual responsibility to push forward the already rapidly advancing knowledge of the technical medical as well as the public health aspects of tuberculosis, and to see that the known facts are disseminated even more rapidly among physicians in general. These functions are best achieved through the work of strong active committees with as wide a geographic distribution as possible and with a diversity of personnel to bring forth all aspects of the problem at hand. There are but few physicians of prominence in the field of tuberculosis or its closely allied specialties who are not active members of the American Trudeau Society. Members give generously of their time and information to work out special problems that may be referred to them or that they consider worthy of further investigation and study.

To provide information that is interesting, accurate and well thought through, to avoid mere novelties without overlooking new developments of intrinsic merit, and to review new phases of old problems is no mean task. This is the work of the Program Committee in arranging the annual meeting. If attendance is an index their efforts have been crowned with success.

As new techniques develop in the field of laboratory medicine in problems allied with diseases of the chest it is essential that the procedures be independently evaluated not by single individuals but by a group of physicians who are actively working in the same field and who have the facilities and personnel to try out the particular method without bias or undue enthusiasm. This is a task of the Committee on Standard Laboratory Procedures, and reports from this group are issued as promptly as possible.

Progress in the fields of diagnosis and treatment is based largely on technical developments in allied sciences. It is not always that these newer developments get to the medical student rapidly and effectively. The Committee on Undergraduate Medical Education, consisting of men who are experienced in teaching and alive to the needs of both student and medical school, is seeking more effective ways to reach this end.

The problem in postgraduate medical education is somewhat different. Practicing physicians are largely creatures of habit; they change but slowly techniques that they have learned and used so long. Only when something is really better, a distinct improvement and not merely different, will it be adopted. The purpose of the Committee on Postgraduate Medical Education is to make available as rapidly as possible knowledge of diagnostic

technics in the field of pulmonary disease particularly where it should be used the most, namely in the office of the physician in general practice. The realization that tuberculosis in its earliest stages when it is most curable, must be actually sought—since it is ordinarily without signs or symptoms—is still somewhat of a mental hazard for men who were taught years ago that fever, cough, sputum and so forth are indicative of tuberculosis, and that proper skill with the eyes, fingers and ears is adequate for diagnosis. As many new methods of using the x-ray become simplified more readily accessible and less expensive, the known facts regarding their effective use need to be widely disseminated. The committee is seeking to analyze the results of actual methods that have already been put into practical use and to get such information not to the tuberculosis specialist alone but particularly to the man in general practice.

New methods of x-ray procedure in the diagnosis of pulmonary conditions are in the course of rapid development. The Committee on X-ray Apparatus and Technique consists of men actively working in the application of x-rays to tuberculosis as a clinical problem as well as those working on technical improvement in existing apparatus. This group is in a position to evaluate the developments of the x-ray and to give this information to the members and the general medical public.

The tuberculosis sanatorium is and should be the focus around which the tuberculosis work of all kinds revolves. As the character of treatment changes, as more technical diagnostic procedures such as bronchoscopy, develop and as surgical collapse therapy grows in extent, there must necessarily be some alteration in the physical plant as well as in the type of medical care available for the tuberculous patient. The Committee on Tuberculosis Sanatorium Standards is now in the midst of evaluating these problems and will be able to report what is considered adequate current practice within the near future.

The policy of the American Trudeau Society, as originally adopted and reaffirmed on numerous occasions, has been that one seeking official certification as a specialist in tuberculosis should have a broad background in internal medicine. To that end the Society has a committee that co-operates with the American Board of Internal Medicine.

Thousands of professional workers, such as nurses, social workers and health officers, as well as many members of the general population, have served as board members of tuberculosis associations, on seal sale committees and in various other capacities. They have a real interest in the developments of technical problems in the field of tuberculosis. To give them authentic advice advisory committees have been set up for the purpose of reviewing such literature of the National Tuberculosis Association as is already available, as well as checking new publications as they are produced. The Committee on Educational Literature and the Committee on Medical Information must necessarily work in very close relation with these large groups of professional and lay persons interested in the general field of tuberculosis. This work to date has been effective, stimulating and productive of much good result.

This in outline, is the general philosophy and its practical application, of the American Trudeau Society. Its work covers those phases of the medical aspects of tuberculosis that are mostly problems for the specialists, as well as those that have special appeal to the physician in general practice. Its effectiveness can continue only so far as both these groups bring to it their current prob-

lems and, working through its committees, bring to bear jointly the sound advice and earnest counsel that is only theirs to give.—Reprinted from *Tuberculosis Abstracts*, January, 1942.

## CORRESPONDENCE

### TRAUMATIC EMPHYSEMA OF THE MEDIASTINUM

*To the Editor:* The clinical note in your number of May 29, by Dr. Gerald L. Gaudrault and Dr. Duncan M. Chalmers on the emergency treatment of traumatic emphysema of the mediastinum had an especial use and interest when read in England, which the march of events now spreads to include America.

In peace time, this condition is but rarely observed, and as a result it more usually receives post-mortem attention than emergency treatment. With the intensive bombing of cities and with the trapping of persons under debris, it is being brought to the notice of many practitioners who are not surgical specialists. It may interest you to learn that I have seen six such cases in one evening (this, even under raid conditions, was an unprecedentedly high figure), and in all the cases the picture was complicated by an intense venous congestion. The casualties had been sitting in the basement of a building built of brick and timber, which collapsed upon them, and when contact was made with them by tunnelling some three quarters of an hour after the bomb-fall, they were buried up to about waist level in brick debris, while the remains of a light concrete ceiling sheltered their heads and shoulders. There had been considerable debris pressure over the thoracic regions. Four of the individuals were dead, and two were moribund.

The two moribund patients showed intense cyanosis and venous congestion, marked dyspnoea, pulmonary oedema, and subcutaneous emphysema in the supraclavicular region and in the sternal notch. The condition in which they were found obviously prohibited a more scientific observation, and they died within some five minutes of being found and before they could be extricated.

It is probable that the condition of the cases described above was already too advanced to be benefited by surgical intervention, but it seems obvious that medical officers must be prepared in these days to carry out the procedures outlined by Drs. Gaudrault and Chalmers. A second point, not mentioned in their paper, and which might be considered, is the benefit accruing from venesection. The relief afforded to the heart and lungs would be undoubted, and the loss of blood and any increase of shock could be compensated for by transfusion at a later and more opportune moment.

The literature on this subject does not appear to be very rich, and in peace time, it seems that most of the experience of this condition would be afforded to surgeons dealing with mine accidents—to which air-raid casualties, seen from the point of view of an urban population, approximate. It would be interesting to learn what men with mine-disaster experience have to say.

## REPORT OF MEETING

### HARVARD MEDICAL SOCIETY

A regular meeting of the Harvard Medical Society was held at the Peter Bent Brigham Hospital on October 14, with Dr. James P. O'Hare presiding.

The case of a thirty-eight-year-old married woman who had entered the hospital six weeks previously because of pain in the right arm was presented. Her past history revealed no evidence of specific kidney disorder or scarlet fever. She was known to have had a negative urinalysis in 1922 while at a sanatorium for bronchiectasis. In 1927, during the seventh month of her first pregnancy, she began to show evidence of toxemia, which persisted until term. At that time, the urine showed a ++++ test for albumin and some erythrocytes, but there was no hypertension. In 1929, during a second pregnancy, she showed a trace of albumin at the fourth month and a phenolsulfonphthalein excretion of 45 per cent at the sixth month, and was delivered normally at term. There were similar findings of marked albuminuria without hypertension during two subsequent pregnancies, but apparent good health from 1935 to 1940. In 1940, the patient was found to have severe hypertension for the first time. During the previous year, there had been increasing fatigue and drowsiness, with frontal headaches, for six months, amenorrhea for five months, increased pigmentation and cramps in the extremities for three or four months and almost daily vomiting for two months. Physical examination revealed a dry, pigmented skin, exophthalmos, fundal hemorrhages without exudate, a normal heart, a blood pressure of 215 systolic, 130 diastolic, a nonprotein nitrogen of 121 mg. per 100 cc, marked albuminuria, and many erythrocytes and granular casts in the urinary sediment. On the tenth hospital day, the patient was given 500 cc. of compatible blood, with subsequent gross hematuria and a later increase in cellular casts in the sediment. Her course was one of increasing drowsiness, decreased vision, increased vomiting and an ever-increasing nonprotein nitrogen.

The case was discussed by Dr. Lewis Dexter, the speaker of the evening, who believed that this course of continued albuminuria, probably originating in the pregnancy, with no previous renal history, is neither common nor rare in a patient with cardiovascular renal disease. Post-toxicemic albuminuria or hypertension seems to be dependent more on the duration of this abnormality during pregnancy than on its severity, and any patient is prone to run fundamentally an albuminuric or hypertensive course until late in the disease. What causes the rather abrupt onset of hypertension after many years of albuminuria, as in this case, is difficult to explain.

The paper of the evening, "Some Recent Advances in Experimental Renal Hypertension," by Dr. Dexter, was a concise evaluation of progress in this field in the light of his own observations. He first discussed the humoral mechanism of experimental hypertension, which for practical purposes had its introduction in the work of Goldblatt and his collaborators, who, in 1934, reported that partial constriction of the renal artery in dogs resulted in prompt and chronic arterial hypertension. Subsequently it was demonstrated by various investigators that some humoral substances from the ischemic kidney must be a causative factor, since the same results were achieved in denervated kidneys and even in sympathectomized dogs. At present, the groups of Houssay, Braun-Menéndez, Fajano, Leloir and Muñoz, in Buenos Aires, and of Pa-

Corcoran, Helmer and Kohlstaedt in Indianapolis, are the foremost in attempting to elucidate this humoral mechanism. To corroborate the humoral aspect, Houssay and his co-workers grafted a kidney into the neck of an animal so that the circulating blood was the only connecting link, and demonstrated that, whereas a normal kidney only rarely caused a rise of blood pressure, an ischemic graft almost invariably did. He then analyzed the venous blood from normal and ischemic kidneys and found both a vasoconstrictor and a pressor substance in the latter. The active pressor substance was isolated and called hypertensionin, and was found to be identical chemically and pharmacologically with the pressor substance produced by the *in vitro* inoculation of renin and blood globulin. Renin had been found in kidneys as early as 1898 by Tigenstedt and Bergmann. Kohlstaedt, Helmer and Page, however, demonstrated that renin alone was incapable of a pressor action unless combined with a certain plasma globulin, which has been variously named precursor and renin activator. Apparently, renin is, or is similar to, a globulin of the enzyme class, and is liberated from the kidney as a result of renal ischemia. Precursor is the substrate, and the term renin activator seems to be a misnomer. This latter component is found only in blood, not in the bodily organs. Hypertensinase is another enzymatic globulin substance, found in practically all the bodily tissues, which acts quickly to inactivate hypertensionin. The Buenos Aires conception of the humoral mechanism of experimental hypertension is as follows:

Page and his co-workers began their investigations with purified renin and proved its inefficacy alone. They have reached essentially the same conclusions as Houssay and his collaborators regarding the nature of the reaction between renin and blood globulin (renin activator) to form a pressor substance (angiotonin), except that they postulate the presence of a so-called renin inhibitor and an angiotonin activator whose presence has not been clearly or unequivocally demonstrated. Their theory, in summary, is

Both the Indiana and Buenos Aires groups have demonstrated the presence of renin in the venous blood of ischemic kidneys. It is rarely present in demonstrable amounts in that of normal kidneys.

Among experiments on the role of amines in the pathogenesis of experimental hypertension may be mentioned the work of Bing on Dopa (dihydroxyphenylalanine). He has demonstrated that this substance is converted by decarboxylase (an enzyme found in renal tissue) under anaerobic conditions to a pressor amine that is probably dihydroxytyramine. Furthermore, its injection into an ischemic kidney results in a pressor effect not found when the same procedure is carried out in a normal kidney. No claim is made for an etiologic role, the ability of the kidney to produce pressor amines may eventually be found to be related to the renin blood globulin, hypertensionin or angiotonin reactions.

Dr Dexter then discussed the relation of experimental to human hypertension. Clinically, there have been at

least temporary cures of hypertension following removal of a unilaterally diseased kidney. Dogs made experimentally hypertensive run a course very similar to that of human beings. Several laboratory experiments, such as the isolation of renin from the human kidney, the changes in various clearance tests and the characteristic hypertensive response in animals to its injection further suggest a close correlation between the experimental and the clinical disease. But the results in one cannot justifiably be translated into those of the other.

Finally, there was a discussion of certain therapeutic agents that have been proposed and tried. An antibody against renin prepared by Wakerlin and Johnson by the repeated injection of pig renin into other animals, was reported to have controlled experimental hypertension. The work was corroborated by Prinzmetal. It is considered a promising lead. Secondly, renin extracts that have long been used therapeutically for hypertension have recently been studied intensively by Grollin in, Harrison and Williams, by Page, Helmer, and Kohlstaedt and by others. These extracts cause a temporary lowering of blood pressure in hypertensive animals and man as long as therapy is continued. Whether such extracts are specific or nonspecific in effect is not clear. It is known that the injection of many foreign proteins lowers blood pressure. In the reports, it is apparent that toxic reactions are sometimes noted when these extracts are injected or administered by mouth. The mechanism by which they lower blood pressure *in vivo* therefore, remains in doubt. *In vitro*, some of the extracts contain hypertensinase (angiotonin inhibitor) as well as renin. It is barely possible that the beneficial effects of the extracts lie in the production of Wakerlin and Johnson's antibodies to renin. Much more work must therefore be done to clarify the mechanism by which renal extracts lower blood pressure.

Tyrosinase, an enzyme that oxidizes phenols, has been studied by Schroeder and shown to cause a rapid fall of blood pressure in hypertensive animals and man. *In vitro*, there is claimed to be destruction of angiotonin. The results appear promising. Hypertensinase is still obtainable only in crude form but is efficacious in lowering the blood pressure of hypertensive animals.

Dr Otto Schales discussed certain enzymatic reactions in relation to that of renin and precursor and spoke in greater detail of the work of Bing and others regarding pressor amines.

Dr Robert W. Wilkins said that, on a recent visit to the Lilly Laboratory for Clinical Research in Indianapolis, he found Drs. Page, Corcoran, Kohlstaedt and Helmer engaged in studies on the depressor substance (angiotonin inhibitor) obtained from extracts of kidney. The administration of this substance to animals or to human beings with hypertension has often been followed by a dramatic lowering of the arterial pressure. At present, the Indianapolis workers are endeavoring to purify this substance, to eliminate toxic side reactions as well as to determine whether or not the presence of renin has anything to do with its action. They are convinced that its effect of lowering blood pressure is not the result of antibody formation. Studies of its physiologic effects show a reversal of the action of angiotonin—that is, an increase of cardiac output (ballistocardiographic) and an increase in renal blood flow with a decrease in the filtration fraction (Smith). Dr. Page and his co-workers are confident that this substance, when obtained in its pure state, will be helpful in lowering the arterial pressure of at least certain patients with hypertension.

Dr. F. A. Simeone reported on observations made during an attempt to obtain an animal for standardization of prospective therapeutic agents. The rapid accumulation of the responsible pressor substance was demonstrated by a hypertensive response as early as three minutes following clamping of the renal artery, with a maximum response in five minutes. The site of action was determined to be peripheral rather than cardiac by denervating the heart and carrying out adrenalectomy. That a multiplicity of substances emanating from an ischemic kidney may account for some of the variable and apparently controversial reports was suggested when some animals had lowering of the blood pressure to shock levels.

Dr. Alan Moritz suggested that, should an inhibitor or neutralizing substance be found, its role in many cases would simulate that of insulin in diabetes, for the irreversible kidney changes would require constant therapy to maintain the status quo.

In reply to a question concerning the role of desoxycorticosterone in the present conception of the etiology of hypertension, Dr. Dexter stated that this hormone is now known to be effective in the hypotension of Addison's disease. Furthermore, after adrenalectomy in dogs, there is sometimes a fall in the concentration of precursor in the plasma. The injection of several of the sex hormones has been reported to elevate the blood pressure of normal animals. The exact relation of the adrenal cortex to blood pressure is, however, far from complete.

## BOOK REVIEWS

*Abnormal Speech.* By E. J. Boome, M.B., Ch.B., M.R.C.P., D.P.H., T.D., and D. G. Harries. 12°, cloth, 162 pp. Cleveland, Ohio: The Sherwood Press, 1939. \$2.50.

The authors present in rather readable style the results of their combined experience with speech disorders. They divide such disorders into three types: the functional disorders of speech, which they consider to be due to imperfect perception of speech or control of the process of utterance in spite of normal organs of speech; the organic disorders of speech caused by malformations, diseases and so forth; and the psychogenic disorders of speech due to nervous disorders. It is difficult to ascertain what the authors mean by nervous disorders. Among the functional defects are delayed speech, lalling, lisping, cluttering and such conditions as aphasia and disorders of phonation that one would expect to find usually when organic disease is present. Among organic defects are considered deafness, palatal defects and dental irregularities. The chief nervous disturbance affecting speech is considered to be stammering. The authors also include a neurotic lisp, a lateral lisp and voluntary mutism as psychogenic disorders.

Throughout the discussion, one meets expressions that are difficult to interpret, particularly those dealing with energy and brain function, in which a tense or sluggish brain producing an unrhythmic movement is described.

Regarding therapy, the authors suggest all sense-training exercises and some motor exercises to help the functional defects. The remedy of organic defects depends on the nature of the defect. The psychogenic disorders are apparently to be helped through exercises for relaxation in which the authors place a great deal of faith. Such exercises are described in detail. Following this survey of abnormal speech, there are chapters on the mentally defective child and his speech and on the "difficult" child and his speech, and a final review of recent progress in speech therapy.

The book is written for use in England, reference being made to the various dialects of that country, and its chief value to an American reader is to serve as a means of being posted on what some workers in the field of speech disorders are doing in another country.

*The 1940 Year Book of Public Health.* Edited by J. C. Geiger, M.D., Dr.P.H. 12°, cloth, 560 pp., with 12 figures and 24 tables. Chicago: Year Book Publishers, 1940.

This is the usual digest of current articles dealing with public health; it is noteworthy that more and more activities are coming within the circle over which the professional public-health worker casts his eye. More than four hundred articles are abstracted, and editorial comments are frequently interpolated. This is the first time that the Year Book Publishers have printed a volume on public health. The result is admirable for those whose particular interests do not lie within the larger field of medicine or for those whose interests are concentrated into smaller fields. The public-health worker himself will probably be better served by the original sources, if he has the time to peruse them. If he has not, he, too, can get a sense of proportion from this reading method.

*Foundations of Neuropsychiatry.* By Stanley Cobb, M.D. Second revised and enlarged edition of the work formerly known as *A Preface to Nervous Disease*. 8°, cloth, 222 pp., with 12 illustrations and 3 tables. Baltimore: Williams and Wilkins Company, 1941. \$2.50.

Because the second edition of this book is based largely on neuropathology, the author has changed the title to fit his material. In addition, he has revised much of the work and slightly enlarged the book. Parts have been rewritten, and in general, the book has been greatly improved. It now forms the best study of its type in English, and should be put in the hands of every medical student. Moreover, the volume will interest a good many thoughtful physicians and will be of particular value to specialists in neurology and psychiatry. The most important addition is the section on psychopathology, which lists the main syndromes of psychiatry. In this short chapter, the author has put a large amount of material in an abbreviated but clear manner. Seldom has the reviewer seen a second edition of a book so vastly improved. Apparently, the author has read the constructive criticisms incorporated in the reviews of the previous edition.

*America Organizes Medicine.* By Michael M. Davis. 8° cloth, 335 pp. New York and London: Harper and Brothers, Publishers, 1941. \$3.00.

This is a thorough and excellent presentation of the relations between a changing medical profession and a changing social order. The points of contact and conflict are discussed in a way that, in the words of the author, "will not satisfy partisans but may promote thought that will diminish partisanship." The weakness of the book is that it presents the point of view of a social worker. For example, it is stated that it is profitable for the optician to turn over a portion of the sale price of eyeglasses to the physician who sent the patient—"This practice is said to be widespread." A medical collaborator would also have mentioned the much greater evil of selling eyeglasses to people who do not need them. The author is more sensitized to the economic aspect of the situation than he is to the physiologic, but his book is nevertheless a helpful discussion.

## CANCER OF THE BREAST

### Results of Surgical Treatment at the Collis P. Huntington Memorial Hospital

CHANNING C. SIMMONS, M.D.\*

BOSTON

THIS paper is a report of the results of the surgical treatment of 135 cases of cancer of the breast observed at the Collis P. Huntington Memorial Hospital up to 1936. It has been made for comparison with several similar reports of cases treated and analyzed in approximately the same manner at the Massachusetts General Hospital.<sup>1-6</sup> The surgery was done by practically the same group of men in both series, or under their guidance. The series is small, but in the earlier years, little major surgery was done at the Huntington Hospital, with the exception of special cases in which the study of new methods of treatment was being made, the patients who required surgical treatment being referred to the Massachusetts General Hospital. Although approximately 100 cases of cancer of the breast are seen in a year in the clinic, the majority are patients with advanced or recurrent disease in whom surgery is contraindicated.

It is somewhat difficult to report this series in a manner that allows comparison with those reported by other observers. The cases have been followed from five to nineteen years. If the results are reported on a strictly five-year basis, as many results are, the percentage of successful cases is much higher than that given here.

The same criterion for operability was employed in this as in the other series mentioned, namely, that the disease must be confined to the breast or the breast and axilla. The presence of obvious involvement of the lymph nodes above the clavicle or of remote metastases rendered the case incurable by surgery. X-ray films were taken of the bones and lungs before operation, to exclude the presence of remote metastases. If remote metastases were found, it was believed that the disease was incurable and that the local tumor could be

held under control by radiation treatment during the patient's life. In a few of the incurable cases, if by simple amputation the growth could be removed with sufficient tissue to render immediate local recurrence improbable, the operation was justified in patients who would rather be rid of an obvious tumor than be continually conscious of its presence and have to report for treatment.

Among the 155 patients who were operated on there were 2 men, an incidence of 1.3 per cent. One of these patients died of another cause in less

TABLE 1. *Analysis of Cases.*

	No. of Cases
Total number of patients	155
Disease limited to breast	55 (34%)
Axilla involved	100 (66%)
Operative deaths	3 (1.9%)
Inconclusive deaths (deaths from other causes in less than five years)	20
Cases available for end result study	135

than five years, and the other is living with recurrence eight years after operation.

In the subsequent discussion, radical operation is considered to be the removal of the entire breast with a large amount of skin and subcutaneous tissue, together with both pectoral muscles and the contents of the axilla.<sup>7</sup>

The term "cure" is applied to patients living without evidence of disease at the time of last examination and at least five years after operation. Those who died postoperatively are considered "dead of disease." This may not be quite accurate, but it makes little difference to the patient whether he dies of disease or as the result of operation. The 20 patients who died of another cause without disease less than five years from the date of operation are excluded as inconclusive in determining the end results (Table 1).

\*Consulting surgeon, Massachusetts General Hospital

There were 3 postoperative deaths among the total of 155 patients who were operated on,—2 due to pulmonary embolism and 1 to sepsis and shock,—the mortality being 1.9 per cent. It is interesting to note that, in one of the patients who died of pulmonary embolism, the source of the embolus at autopsy was found to be the iliac and not the axillary vein.

The 135 cases suitable for study of the end results again have to be divided, possibly arbitrarily, but in a small group classed as "palliative" the operations were performed usually in conjunction with radiation treatment and with no hope of cure by surgery alone. It does not therefore seem fair to include them with a group in which surgical cure was considered possible. A second group, "incomplete operations," composed of elderly people on whom a simple amputation was done, usually under local anesthesia, to remove a tumor apparently confined to the breast, is also considered separately.

RADICAL OPERATIONS

Excluding the groups with palliative and incomplete operations, there were 116 cases in which a radical attempt at surgical cure was made, with cure of from five to nineteen years in 50 cases (42 per cent). In the group in which the axilla

FIGURE 1. Results of Radical Operation for Cancer of the Breast.

was not involved (42 cases), there were cures in 31 cases (74 per cent), and in those with involvement of the axillary lymph nodes (74 cases), there were cures in 19 cases (25 per cent). These figures correspond closely to those reported in the last two series from the Massachusetts General Hospital: namely, 1927 to 1929, 43 per cent, and 1930 to 1932, 45 per cent. The percentage of cures at yearly intervals is shown in Figure 1.

For comparison with the figures reported by other observers on a strictly five-year basis, the cures by surgery alone in the entire group are 55

per cent, and in cases without axillary involvement, 85 per cent (Table 2). The latter group, however, includes cases cured by simple amputation in which the result indicates that the axilla

	%	%
All cases	55	42
Cases without axillary involvement	85	74
Cases with axillary involvement	35	25

was not involved. No patient in whom the lymph nodes were uninvolved developed recurrence after five years.

The number of cases of late recurrence is impressive (Table 2). I believe that the percentage

FIGURE 2. Logarithmic Chart Showing Survival Rates for Patients with Cancer of the Breast.

of cures would be much lower if all cases had been followed for ten years. Formerly, it was estimated that 15 per cent of patients living without evidence of disease at the end of five years would eventually die of recurrence, but in this series the percentage is larger: thus, of 20 patients living at the end of eight years, 7 eventually died of metastases. It is only fair to state, however, that 4 of these presented recurrence at an earlier date and lived with known disease four, five, six and seven years respectively, 1 eventually being killed in an automobile accident. This group emphasizes the vagaries of the disease and the difficulty of evaluating any form of treatment.

The cases have been plotted on a logarithmic chart (Fig. 2), which allows for the number of patients followed for varying lengths of time and the numbers dying of disease yearly. On this chart.

there is a constant percentage of deaths up to ten years. The dotted line represents the life expectancy of all women after the age of fifty-two. The solid line indicates the yearly survivals of the cases of cancer of the breast; it includes only those who died of the disease. The broken line, from Nathanson and Welch,<sup>8</sup> represents the expectation of life in patients with cancer of the breast who have received some form of treatment. The report of Daland,<sup>9</sup> who followed 100 untreated cases of *cancer of the breast and found that 26 per cent were living at the end of five years*, should also be borne in mind in estimating the value of any method of treatment.

This series is of course small, and it would be interesting to follow a large group for from ten to fifteen years, but the difficulty of doing this accurately is practically insuperable. The figures imply, however, that a patient with cancer of the breast cannot be considered as certainly cured even though living without evidence of disease five years after operation. On the other hand, no patient in whom the disease was limited to the breast developed recurrence after the fifth year.

#### *Effect of Duration of Disease before Operation on End Results*

The median duration in cases in which the disease was limited to the breast was two months, and in those with positive axillary nodes, nine months. The average duration in these two groups was six and nine months respectively. The median duration gives a much more accurate picture of the effect of delay on the extent of the disease and the possibility of cure than the average duration, for if the latter figure is employed, one or two cases of very long duration will influence the figures and give an erroneous impression. The figures given are essentially the same as those reported in the publications previously referred to.

The delay of adequate treatment is usually due to the patient. So far as could be determined, 19 patients received poor advice from the first physician consulted. This is discouraging, considering the amount of educational work that has been carried on in Massachusetts by the Department of Public Health for the last fifteen years. When the delay, or duration of disease, was compared with the degree of malignancy as determined by the pathological examination of the specimen, it was found that in 33 per cent of cases of low malignancy, 38 per cent of medium malignancy and 54 per cent of high malignancy, the patient sought advice within three months. This may be interpreted to mean that a rapidly growing tumor at-

tains a size that causes concern to the patient more quickly than one of low malignancy.

#### *Effect of Extent of Disease on End Results*

The extent of the disease, that is, whether it is limited to the breast or has extended to the axillary lymph nodes, is apparently the most vital factor in the prognosis. In 36 per cent of the cases, the axillary lymph nodes showed no evidence of disease on pathological examination, and 74 per cent of these patients were cured for from five to eight years; if a strict five-year limit is employed, the cures were 85 per cent. In 66 per cent, the axillary nodes were involved, and the percentage of cures was 25. Unfortunately, the extent of the lymph-node involvement is not stated in the pathological reports; 35 per cent of patients, however, were living without evidence of disease at the end of five years. Of the patients living at the end of five years, 22 per cent eventually died of disease. Since many patients have not been followed for much over five years, it is probable that many now living, apparently free of disease, will eventually develop recurrence. As has been previously mentioned, no patient with uninvolved axillary lymph nodes developed recurrence after five years.

A study has been made to determine the value of physical examination in estimating the extent of axillary involvement. In 59 cases in which it was stated in the record that no axillary lymph nodes could be felt, cancer was found in 25, representing a 40 per cent error. When the nodes were palpable, 80 per cent later proved to be cancerous. The evaluation of the extent of the disease by clinical means alone is therefore subject to considerable error.

#### *Effect of Degree of Malignancy on End Results*

In previous communications, all tumors have been graded pathologically into three degrees or grades of malignancy,—low, medium and high,—depending on the degree of differentiation of the cells, as suggested by Broders<sup>10</sup> in 1920; it was found that, with the exception of the extent of the disease, this was the most important factor in the prognosis. In a few cases in this series, specimens were not available for review, but the relation of the index of malignancy to the results has not worked out as in previous analyses. The largest number of cures occurred in the cases of low malignancy, but there was a greater percentage of cures in tumors of high than in those of medium malignancy. The results are shown in Table 3.

It should be noted that in no tumors of low malignancy (10 cases) were the lymph nodes diseased, and that all the patients were cured. Three

other cures were obtained by simple amputation in cases of low malignancy.

In 6 cases, the cancer arose from a papillary cystadenoma, and the axilla was not involved; 5 of these were of low malignancy and 1 of high, and all the patients were over fifty years old.

Cancer was associated with Paget's disease of the nipple in 5 cases, in 3 of which the nodes were

TABLE 3. *Relation of Malignancy to Cure.*

DEGREE OF MALIGNANCY	ALL CASES		CASES WITHOUT INVOLVED NODES		CASES WITH INVOLVED NODES	
	NO.	CURES %	NO.	CURES %	NO.	CURES %
Grade 1	10	100	10	100	None	—
Grade 2	72	38	24	54	48	30
Grade 3	24	50	8	100	16	25

involved; in 1 of these, the patient was cured. The 2 patients without axillary involvement are well.

Seven cases were classed as colloid cancer, 4 of which are suitable for end-result studies. In 3, the nodes showed disease, and the patients are dead. The patient with uninvolved nodes is living.

Three cases of so-called "inflammatory cancer," all in relatively young women, were considered incurable by surgery alone when first seen. Some form of surgery was employed, however, in conjunction with radiation treatment; all the patients are dead.

#### *Effect of Age on End Results*

It has often been stated that the prognosis of cancer of the breast is much worse in women under forty than in elderly women. The groups of cases from the Massachusetts General Hospital have always failed to prove this except in the last series analyzed, in which, however, it was shown that the prognosis really depended on the degree of malignancy and not on the age of the patient.<sup>6</sup> The present group, although small, confirms the previous findings, since the age of the patient had little relation to the end result.<sup>11</sup> Of 16 patients under forty years of age, 10 are living and 6 are dead, whereas in 19 cases over sixty, 10 are living and 9 are dead. In the younger group of the patients living, the disease in every case was confined to the breast, but in only 3 was the tumor graded as of low malignancy. In the elderly group, 5 of those living showed tumors of low malignancy, and 5 cases were of higher grades of malignancy, in which 3 showed axillary involvement.

#### *Effect of Biopsy on End Results*

A biopsy at the time of operation to verify the clinical diagnosis was performed in 28 (25 per cent) of the cases. Fifty per cent of this group

of patients are well. The results are slightly better than those of the full series, as would be expected, for biopsy was performed only when the clinical diagnosis was questionable. In 26 per cent of these cases, the disease was later found to be limited to the breast, and in the remainder the lymph nodes were involved. This illustrates the difficulty of making a correct clinical diagnosis even in the presence of relatively extensive disease. In the two groups, with or without lymph-node involvement, the comparative results were similar to those in the general series in which no biopsy was performed.

To obtain a specimen, it has been the practice to make an incision directly into the tumor, and if it proves to be cancer, the wound is packed with formalin gauze and closed before the radical operation is performed. Removal of a specimen for diagnosis under local anesthesia and performing the radical operation at a later date is considered a dangerous procedure, for although it is difficult to obtain definite statistical evidence, it is believed that the results are not so satisfactory as those when the biopsy is followed immediately by radical operation. In most cases, the diagnosis is obvious when the tumor is incised.

#### *Site of Recurrence*

The principal site of recurrence was known in 67 of the patients dying of disease, although in most cases the recurrences were multiple. In 95 per cent of the entire group, there was a local recurrence. The commonest remote sites were in the bones or lungs (23 per cent each), although practically every organ of the body was diseased in some patients.

The 14 cases in which recurrence was late, that is, after five years, are of particular interest. In 4, the disease had been limited to the breast, and the recurrence was remote; there was evidence of recurrent disease before the fifth year, however. One patient showed evidence of disease of the lung five years after operation but lived for seven years, or twelve years from the date of operation. Of the 10 patients with involved lymph nodes who died of late recurrence, local recurrence appeared at the end of six years in 2, and in 8 the recurrence was remote; 5 of the latter lived for nine years or more. There was no demonstrable relation between the extent of the disease, the degree of malignancy or the age of the patient and the development of late recurrence.

#### PALLIATIVE OPERATIONS

All the 9 patients in this group showed extensive disease or presented rapidly growing tumors,

and were considered incurable by surgery alone. Radical operation was done as a supplement to radiation treatment. Three were cases of what may be called "inflammatory carcinoma." Of this group, 1 patient died as a result of operation, and the other 2 died of the disease.

#### INCOMPLETE OPERATIONS

Of the 10 patients in whom amputation of the breast without dissection of the axilla was performed, 4 were living without disease five or more years after operation. All were poor surgical risks, and in 6 the operation was performed under local anesthesia. At first glance, these results are as favorable as those following radical operation, but in a study of the cures, 3 cases had tumors of low malignancy that arose in papillary cystadenomas, and in 1 case the tumor was small. In no case were the lymph nodes involved, and the 40 per cent cures should be compared with the 74 per cent cures following radical operation in the same group.

#### IRRADIATION

The general policy of the hospital has been not to employ radiation treatment before operation or as a postoperative measure unless the disease was more extensive than had been anticipated and there was a possibility that tumor tissue had been left in the axilla. The rationale of preoperative irradiation to inhibit the growth of cells is understandable but I do not believe that the results following operation on a tumor that at one time was considered inoperable but has diminished in size following irradiation will be satisfactory except in an occasional case.

If a sufficient dosage of postoperative irradiation is given to destroy cancer cells, permanent damage to the skin may follow, and small doses do not accomplish results. Furthermore, it is difficult to see how recurrences can be affected by irradiation of the chest, for in only 9.4 per cent of the cases were they local—the figures from the Massachusetts General Hospital series show 7.5 per cent local recurrence. In recurrent cancer, however, radiation treatment applied to the lesion is of great value.

In this series, postoperative irradiation was employed in 2 cases without axillary involvement; both patients are well. It was also employed in 11 patients with involvement of the axillary lymph nodes, 3 of whom are well. These figures are approximately the same as those for the entire group. In 13 cases, an artificial menopause was brought about by irradiation. In 5 of these, the disease was limited to the breast, and 4 patients

were under forty years of age—these 4 are living without disease. In 8 patients, the lymph nodes were involved, and 3 of these are living. This is a small group, but the figures vary but little from those of the entire series.

An attempt has been made to study and tabulate the results of treatment of the advanced cases by irradiation; although definite impressions have been obtained of its value in inoperable and recurrent cases, it is impossible to make any rules for treatment or to report fairly the results. In practically all, symptomatic and temporary relief was obtained, but when the vagaries in the course of the disease are considered, it is very questionable if life was actually prolonged, and certainly there have been no cures.

#### SUMMARY AND CONCLUSIONS

The results of the surgical treatment of 135 cases of cancer of the breast at the Collis P. Huntington Hospital are reported. The end result is known in every case, and all surviving cases have been followed from five to nineteen years.

One hundred and sixteen of the patients underwent radical operations. Forty-two per cent of them were living without evidence of disease five or more years after operation. In the cases in which the disease was confined to the breast, there were 74 per cent cures, and in those showing involvement of the axillary nodes, 25 per cent. On a strictly five-year basis, the cures were 55 per cent for the series, 85 per cent for the cases without axillary disease, and 35 per cent for those with involvement of the lymph nodes. The most significant factor in the prognosis is therefore the extent of disease.

The pathological index of malignancy is probably, next to the extent of disease, the most important factor in the prognosis, although the figures in this series are not so conclusive as those of others; however, it is admittedly more difficult to grade an adenomatous than a squamous-cell tumor.

Of the 64 patients apparently well at the end of five years, 14 (22 per cent, or 12 per cent of the entire group) died later of recurrence. Of 20 patients living over eight years, 7 eventually died of cancer. Because many of the cases were not followed for more than five or six years, it is probable that some of these will develop a late recurrence. On the other hand, the 4 patients without axillary involvement who died of disease after five years all presented evidence of metastases before the fifth year. It therefore appears that patients in whom the axillary lymph nodes are not involved and

who show no evidence of recurrence within five years may be considered permanent cures.

The age of the patient in itself has no relation to the curability.

Recurrence in the operative field in suitably selected cases is relatively rare.

## PSYCHIATRIC ASPECTS OF ULCERATIVE COLITIS\*

GEORGE E. DANIELS, M.D.†

NEW YORK CITY

A RECURRENT, wasting and often fatal disease with no established etiology presents a challenge on all medical fronts. So far, attempts to prove that a specific organism is the primary cause of ulcerative colitis have failed. General skepticism concerning the efficacy of the numerous medical procedures extant serves to emphasize the stalemate that has attended progress in the basic knowledge and treatment of this disease. Surgery is generally reserved for cases in which conservative measures have failed; the mortality rate is high after surgical intervention, and a successful operation generally leaves the patient with the annoyance of a permanent colostomy.

Sometimes, an entirely new approach reveals surprising results in such a situation, and this can truly be said to have occurred when a psychiatric approach was applied to the study of what is commonly known as nonspecific, or idiopathic, ulcerative colitis. The few authors who have thoroughly investigated the subject consider that emotional conflict furnishes the most consistently recurring factor. The degree to which it may supply the missing etiology in a large group of cases still remains to be proved. It is not my purpose to attempt such proof, but to present a few facts that may be of general use to the practitioner.

Ulcerative colitis appears in a fulminating form that runs a few weeks and is often entirely resistant to treatment, and occurs in a chronic form with remissions during which the patient may be comfortable and fairly active. The mortality fig-

ures range from 33.5 per cent by Hardy and Bulmer<sup>1</sup> in all cases over a period of twelve years, to 10 per cent by Barga and Buie<sup>2</sup> in a ten-year period at the Mayo Clinic. Spriggs<sup>3</sup> reports 20 per cent in nineteen years; Buzzard, Richardson and Turner<sup>4</sup> and Hern<sup>5</sup> give the figure as 28 per cent. Of those patients who survive and are not surgically treated, about 75 per cent are considered well enough during remissions to earn a living. Attacks often last for many months. Anything that contributes to cutting down the attacks obviously represents a substantial economic saving, as well as a reduction of suffering.

In 1930, Murray<sup>6</sup> first described psychogenic factors in ulcerative colitis. He was, at that time, connected with the Constitution Clinic at the Presbyterian Hospital, New York City, where various gastrointestinal conditions were being studied from various angles, including the psychologic, by Dr. George Draper's panels. Murray was struck by the well-marked time relation between the outbreak of an emotional disturbance and the onset of symptoms. He published the results of investigation of 12 cases, 4 of which were given in some detail. In another case, published later, he<sup>7</sup> gave a brief analysis of the psychologic factors involved. In this case, the patient's first memory (at the age of three) was of seeing her mother's coffin in the house. Murray followed out the effect of the attachment of the patient's libido, at this early age, to a dead imago. He emphasized the role of fear in the cases studied, and pointed out that diarrhea is a recognized infantile reaction to fear. He found marked emotional immaturity in these cases. Of 7 men, all were tied up with their mothers, except

\*From the Department of Psychiatry and the Department of Medicine, College of Physicians and Surgeons, Columbia University.

†Clinical professor of psychiatry, College of Physicians and Surgeons, Columbia University; assistant attending physician, Presbyterian Hospital.

1, who had found a mother substitute in an older sister. None of the men were married. Murray noted the most frequent conflict to be that between the attachment to the mother and the desire to get married. He emphasized the fact that it is not a sudden fright that causes the difficulty, but a new situation, which thereafter keeps the patient in a constant state of apprehension. Symptoms are an expression of resentment and hatred. The character traits can be recognized as those described as anal, with masochism evident, sadism concealed. This author expressed the opinion that the psychologic factors in ulcerative colitis are similar to those long recognized in simple diarrhea and mucous colitis.

Sullivan<sup>8</sup> recognized one of the patients in the Yale Hospital, New Haven, as one of those described in Murray's first paper. This patient had had a marked conflict over her forthcoming marriage. According to the history subsequently taken by Sullivan, she did marry a few weeks after leaving the Presbyterian Hospital, and immediately had had a return of diarrhea with blood. Murray had obtained significant facts from this patient relative to fear of childbirth, from which her mother had died. She was convinced that if she had a child, this would also be her fate. She was an ardent Catholic, and marriage had not been consummated during the first two years for fear that she would become pregnant. While she was in the New Haven hospital, her fear of pregnancy was gone into in an attempt to recondition her. She was given a gynecologic examination, and reassured. It was later learned that she had died two days after childbirth. Pregnancy had occurred immediately following her discharge from the hospital, and during it she had developed toxemia and a kidney disease. She had had no return of her colitis. As one comes to know ulcerative colitis cases, one believes that there was more than chance in the manner of this patient's death. Except for this one case, the Yale group reported excellent results with psychotherapy.

In 15 cases, Sullivan<sup>9</sup> found definite character traits. A sense of neatness was frequent, and most of the housewives were of the "fussy" variety. The outstanding characteristic was emotional tension. Ten patients of the series had prolonged tension, and it was this "stewing over things," as in Murray's cases, that was considered the important part of the condition. Eight of the 15 patients gave histories of financial worry, and in 6 cases, money matters played a prominent role in the total problem presented. Another very frequent factor was a close attachment to the mother or some other relative. In 2 wives and 1 husband diarrhea re-

lated to pregnancy and childbirth was demonstrable, in 2 others, it appeared chronologically, but the psychologic relation was not clear. Sullivan emphasized, as Murray did, the close relation between an actual precipitating event and the outbreak of diarrhea. In 11 of the 15 cases, the latter was within forty-eight hours of the former. In the remaining 4, the exacerbations of the disease were shown to be related to the nuclear conflict. Because of this coincidence, it was possible to concentrate on the emotional situation just prior to the attack.

Since the communications of Murray and Sullivan, increasing attention to the emotional factor in ulcerative colitis has been paid in the literature, emphasis is also beginning to be placed on the value of treatment of this factor. However, the only other systematic study of personality factors in ulcerative colitis recently reported is that undertaken by Wittkower,<sup>10</sup> who made a study of 40 unselected patients with ulcerative colitis in the Tavistock Clinic at St. Bartholomew's Hospital in London. Psychiatric disorders occurred far more frequently in these cases than in the average population. Such disorders were found to have antedated the colitis, and were so gross that a special control group was considered unnecessary. Carefully dated histories and verification with relatives showed that disturbing events preceded the onset, recurrence and increase of symptoms far enough to be more than a matter of chance. Twenty-eight of the 40 patients reported remissions of the disease. In 17, one or more relapses coincided with disturbances in their lives, usually with some external event. Many patients noticed a decline of their mental symptoms with the increase of their bodily ones. In 28 of the 40 cases, a clear-cut emotional trauma was considered serious enough to have been the precipitating factor of colitis. In 11, acute emotional stress, and in 17, prolonged emotional stress, ushered in the disease. The remaining 12 included those cases with the greatest psychologic deviation and those in which none was discovered. In 7, serious occupational, and in 4, severe financial difficulties preceded the onset. In 2 cases, colitis occurred under the strain of a forthcoming examination, in 6, there were domestic difficulties and in 2, dramatic love affairs were responsible. Sexual conflicts of an immature nature were important in 4. In 3 cases, colitis began in the course of pregnancy, and in 1, fear of labor was a major factor. Wittkower found no uniform personality make up, but his cases fell into three groups, with common characteristics within the group, a fourth group consisted of the miscellaneous personality types. The

first group was characterized by obsessional traits, the second, which was made up completely of women, by hysterical traits, and the third by depressive or schizoid trends. The personalities in childhood coincided with those in adult life, except that there was often an exaggeration of characteristics after maturity.

Sullivan<sup>9</sup> reports the most systematic attempt at treatment of ulcerative colitis along psychologic lines. The Yale group found by experience that patients could be helped more by procedures directed toward improvement of their personal problems than by therapy directed toward the colonic symptoms. This treatment was carried on on the medical wards by the general medical staff, and a psychiatrist was consulted only in the more difficult cases. Usually, the first month was spent in working up the laboratory data and establishing the general medical regimen. The patients were placed on a low-residue diet, with additional vitamins, and were given symptomatic therapy with bismuth, kaolin and belladonna. None of these procedures seemed to give more than symptomatic relief. The disease was either unchanged or aggravated until progress could be made along psychotherapeutic lines. Sullivan emphasizes the fact that weeks must be spent in getting the confidence of the patient, and that the problem would be very much more complicated if it were not for the amazingly close chronological association between an emotional episode and the onset of bloody diarrhea. He stresses the time necessary to get at even the conscious psychologic difficulties, and gives examples. He makes 60 per cent a conservative estimate of the incidence of ulcerative colitis on a psychogenic basis.

During the last ten years, I have seen 25 cases of ulcerative colitis at the Presbyterian Hospital. These have not been unselected cases, since most of them were referred by physicians for psychiatric consultation and treatment. A number of them have been followed for five to eight years, and a few have been studied intensively. Of 14 such cases, which comprised 2 men and 12 women, 8 showed a pathologic attachment to a relative; in 6, the death of this relative had been of paramount importance. Indecision about marriage was marked in 2 unmarried members of the group, and in 2 others, engagement and marriage were the precipitating causes of the first attack. In 2 cases, the first onset of symptoms was associated with childbirth, which also played a prominent role in another. Money difficulties had special significance in 4 cases. As a group, the patients were not well-adjusted sexually, although this did not generally stand out as the presenting problem.

The following cases illustrate typical findings in emotionally conditioned ulcerative colitis. Because Case 1 deals with one of the most frequently encountered therapeutic problems, — emotional emancipation from domineering relatives, — it is given in some detail. Two other cases of this series, which present a comparable family situation, have been reported elsewhere.<sup>11, 12</sup> In Case 2, the disease was precipitated by childbirth under conditions that kept alive a chronic conflict. In Case 3, the loss of a parent, with resulting depressive and suicidal trends, played the determining role.

### CASE REPORTS

CASE 1. F. A., a 26-year-old Italian housewife, was admitted to the Presbyterian Hospital in February, 1938, for bloody diarrhea. She first had intermittent attacks of diarrhea with mucus and blood associated with abdominal pain 6 years before entry, when she had been hospitalized for 7 weeks. This was followed by two more attacks within a year, both requiring hospitalization — one over a 2-month period. The patient was well for a year preceding the attack that brought her to the hospital, except for the occasional appearance of blood in the stools. A month later, when she reached the hospital, she was having twenty stools a day, with blood and mucus and a moderate amount of pain.

Physical examination was negative except that the abdomen was tender to palpation over the sigmoid and ascending colon. The liver had descended to the costal margin and was tender on palpation. The spleen was not palpated. The temperature was 102°F., the pulse 120, the respirations 20, and the blood pressure 120/80.

Examination of the blood showed a red-cell count of 4,350,000 with a hemoglobin of 79 per cent, and a white-cell count of 10,000. The stools contained mucus and gave a ++++ guaiac reaction; no ova or parasites were noted. *Escherichia coli*, *Streptococcus viridans* and *Clostridium welchii* were obtained on culture. A barium enema showed an irritable proximal colon; the descending colon appeared smooth and suggested ulcerative colitis. Proctoscopy revealed that the mucosa bled readily, was grayish brown and edematous, and was sprinkled with numerous small and moderate-sized ulcerations. The basal metabolism was -5 per cent.

The patient's attending physician in the hospital, suspecting that emotional factors were contributory in this case, referred the patient for psychiatric consultation and treatment, which were undertaken while she was still in the hospital. She was thoroughly co-operative, and volunteered the information that she herself had noticed a definite relation between emotional upsets and the attacks of diarrhea, which were usually preceded by a prodromal headache.

The patient was put on a low-residue diet and a course of pectin-agar, then of Anayodin, and then of sulfanilamide, supplemented with luminal, tincture of belladonna, paregoric and bismuth subcarbonate. She ran a fever of 103°F. intermittently, with a fairly persistent leukocytosis and elevated sedimentation rate. For 6 weeks, she passed from ten to twelve stools a day; after this, the number of stools gradually diminished until finally, by the 9th week, there was only one a day. There was no

definite correlation between clinical improvement and the medication administered

During the first psychiatric interview, the patient immediately began a discussion of the family, and this continued to be the main subject of the contact. She had been married at 17, and her husband at 21, against the wishes of both families, who, however, later accepted the marriage. She and her husband lived with his family, who did everything possible for them. Her husband was the pet of the family, the youngest of a number of unmarried siblings. His family immediately adopted the patient, and it became impossible for her and her husband to develop any real feeling of independence. Even when they went to live alone, his family supplemented their income and belongings, and were sensitive to any objections. They did not like her family, and because of this her mother visited her only once in 2 or 3 months, although she did not live far away, and she usually found some member of the husband's family there when she did come.

Two weeks before the attack that brought the patient to the hospital, one of her sisters in law had visited her and had made some gestures of reconciliation in connection with a quarrel that had developed during the Christmas holidays. The patient's husband was thoroughly in sympathy with her wish to become independent of his family, but there were so many of them that she had begun to believe that it was hopeless and that she might as well give in.

After several psychiatric interviews, an underlying depression came to the surface. The patient had periods of crying and expressed the opinion that her case seemed hopeless, although this had not been her attitude when she entered the hospital. It became quite clear, with further observation, that this hopelessness largely referred to the family situation. The patient told in some detail of the way in which her husband's family tyrannized her, especially after the outbreak of her first attack of colitis. They tried to prevent her going out at all on the basis of her health. She feared that, whenever she returned home from any excursion, one of her husband's family would be there to administer a rebuke. On one occasion, the mother-in-law informed a sister-in-law that the patient had gone to visit her mother. The sister-in-law promptly went to the patient's home, awaited her return and told her that she had just been talking to a physician, who said that it was not good for the patient to be out. When the patient intimated that she understood the ruse, the sister-in-law became very angry. The patient felt that before her illness it had been one thing to stand up for her rights, but since there was danger of recurrences of her colitis she did not dare to be so outspoken as formerly. The family was getting back the hold they desired. (One is reminded of the statement of another patient in this series,<sup>6</sup> whose mother would rather have her sick and at home than well and away.)

The history also showed that the couple had practiced coitus interruptus for the preceding 4 years, and because there was a history of anxiety and the possibility that some of the patient's symptomatology might be on the basis of an anxiety neurosis, she and her husband were advised about better sexual hygiene, and she was given an appointment at the Contraceptive Clinic.

The patient made a gradual recovery from this attack. After a few months in another locality, she and her husband moved back to the vicinity of his family because of school opportunities for their children, but this time they were on an entirely independent economic basis. The patient had begun to assert herself and had gained

courage to stand up for her rights—among others, the privilege of seeing her own family when she wished to without the criticism of his family. A year after hospitalization, she believed that the relation with her mother in law and sisters in law was improving. However, one brother in law still refused to speak to her, and another was very insulting and was outraged if any of her friends or family visited at the same time he did. When the patient explained to him that he had no right to act in this way toward guests in her own home he parried by reiterating how good he had been to her when she had been ill. She pointed out that this had nothing to do with the present problem, and he reluctantly accepted this point of view and was polite and friendly on succeeding visits. At this time, she seemed to be working gradually through her enslavement to her husband's family.

In the fall of 1939, she reported that she had been entirely free from symptoms for 3 months. She had had a slight recurrence, which could be laid to a return of the family difficulty. A great deal of her improvement was referred to the fact that a sister in law had returned with her baby to the parental home, and that the family had turned its attention and domination from the patient to this woman and her child. The patient was much relieved that her husband's family had some other object for their attention than herself. She was feeling and looking very well.

Three months later she reported a return of bleeding and she was convinced more than ever that this was related to the old family difficulty. She found that one of the sisters in law, although very nice to her face had been telling petty stories that tended to put the patient at odds with other members of the family. The patient then came to the conclusion that the only solution was to cut off entirely from her husband's family because attempts at reconciliation were successful only for a short time and she believed that the difficulties were incurable with which her husband concurred. She did not harbor resentment, but realized that the hold they had had on her when she was first married arose because of the affection that she had for them. This, she felt, had been destroyed by the things they had done and she did not anticipate that separation from them would any longer cause difficulty. It will take time to determine whether this situation is actually solved or only ameliorated.

CASE 2 S. M., a 48 year old, obese Jewish housewife, was admitted to the Presbyterian Hospital in February 1937, complaining of intermittent diarrhea of 11 years duration with two to six watery movements with mucus each day. The history stated that several attacks had been precipitated by emotional traumas, that diarrhea had first occurred 10 days after the birth of her first child and that blood had appeared in the stool following the birth of her second child.

On physical examination, the fundi showed sclerosis the thyroid gland was palpable but not enlarged and the abdomen was obese and pendulous, with slight tenderness in the left lower quadrant but no spasm. No masses or viscera were felt. The heart and lungs were normal. The temperature was 99.4°F, the pulse 96, the respirations 22 and the blood pressure 150/85.

Examination of the blood showed a red-cell count of 3,700,000 with a hemoglobin of 75 per cent and a white cell count of 8200. The nonprotein nitrogen of the blood serum was 36 mg per 100 cc. The stools gave a ++ guaiac reaction and showed no mucus. The urine was normal. The blood Wassermann reaction was negative. Proctoscopy showed lesions typical of ulcerative colitis. A

barium enema showed advanced ulcerative colitis. X-ray study revealed small areas of translucency in the tip of the gall bladder, indicating calculi, but with normal physiologic functions.

During the 10 weeks in the hospital, the case was considered interesting because of its chronicity without any demonstration of marked anemia or evidence of chronic disease on inspection. There was no relief from bismuth, diet or rest in bed. The patient was given a series of four autotransfusions, with radiation of the blood by ultraviolet light. These did not result in any improvement, and she was discharged to the Out-Patient Department, where she was followed.

Information obtained 6 months later showed that the patient had been unable to become pregnant during the first 14 years of marriage. A year and a half before her pregnancy, she had taken treatment for sterility, and at about the same time she acquired a lover, since her husband had proved sexually unsatisfactory to her. She was convinced that her first child had come from this union. She had been unable to believe that she was pregnant for some time, but when convinced of it she had been of two minds. One was joy at the idea of having a child, and the other was conflict and conscience over its paternity. This conflict came to a climax after the child's birth, and was increased by doubts whether it would live. The child did live, and is now perfectly healthy. Its coming had been a considerable source of interest to friends and neighbors on account of the patient's 14 years of barrenness. Her husband had likewise been pleased, and never suspected that the child was not his. The patient stated that she had never told anybody about the situation, not even her sister, but that *not a single day had passed without its being on her mind.*

The patient was certain that her husband was responsible for the second pregnancy, which occurred after 6 months. She was not clear why she had this child except that she took no precautions. She considered the interval between the pregnancies too short, and was resentful because she had had no rest from the first.

The patient did not improve dramatically following this revelation, but did seem considerably relieved in her mind. She continued to hold her own, was able to do her housework, and had brief periods of normal stools. Her lover died about a year after her discharge from the hospital. The environmental situation held little hope of improvement, and further psychotherapy did not seem to be the answer to the problem. The patient was referred to Dr. Thomas T. Mackie's service at the Roosevelt Hospital, New York City, and a report from that hospital stated that during the following year her course had been one of slight improvement, with minor periodic exacerbations. No infective agent was revealed.

CASE 3.\* L. B., an 11-year-old girl, was admitted to the Babies Hospital, New York City, in July, 1937, because of chorea and diarrhea. One sister was reported to have had intermittent attacks of diarrhea, with blood-streaked stools, for the previous 2 years. In March, the patient had begun to have intermittent attacks of loose stools, with some lower abdominal pain. About June 1, the mother had noticed rectal bleeding, with flecks of blood in the stools. A private physician had advised admission to another hospital, where x-ray studies of the colon were negative. During the 2nd day of her stay in this hospital, the patient had developed generalized choreiform movements. She had been removed from this hospital and

given three injections of triple typhoid vaccine at home. The chorea had progressed for the 10 days prior to admission to the Babies Hospital, and the child had become unmanageable at home.

Physical examination showed an asthenic, undernourished child who was thrashing about the bed with violent choreiform movements involving the entire body. On the skin about the angles of the mouth were patchy, vesicular, somewhat encrusted fissures, spreading inside the mouth and involving the buccal mucosa and the mucous membranes beneath the tongue, where there was an irregular, dirty, ulcerated lesion about 1 by 2 cm. The heart was not enlarged. A soft apical systolic murmur was present. The abdomen was scaphoid. The liver edge was palpable just at the costal margin. The spleen was not palpated. There were no gross neurologic changes. The temperature was 100.2°F., the pulse 120, the respirations 18, and the blood pressure 105/70.

The blood showed a red-cell count of 3,000,000 with a hemoglobin of 56 per cent, and a white-cell count of 18,150 with 77 per cent polymorphonuclears and 21 per cent lymphocytes. Subsequently, after gross hemorrhages, the red-cell count dropped to 1,500,000 with a hemoglobin of 28 per cent. The urine showed a faint trace of albumin, with much sediment and debris and granular casts. The stools were negative for pathogenic organisms. A smear of the mouth ulceration revealed no Vincent's organisms. Stool examinations frequently showed occult blood, but no ova or parasites.

On sedation with Chlorotone over a 2-week period, the choreiform movements entirely subsided, but the diarrhea continued unabated, with nine to eighteen stools a day. Proctoscopic examination showed granular rectal and sigmoid mucosa, with multiple points of bleeding but no large ulcerated areas. Because of rapidly developing anemia, the patient was given a series of citrated transfusions, with some rise in the red-cell count and hemoglobin. She was placed on a high-carbohydrate diet and given concentrated vitamin preparations, both by mouth and parenterally. Two weeks after admission, she became maniacal, thrashed about the bed and was uncontrollable. A neurologic consultant attributed the behavior to Chlorotone poisoning, and the drug was discontinued; the maniacal symptoms disappeared, and no further choreiform movements were noted. One month after admission, the patient had several large massive hemorrhages, amounting to between 300 and 500 cc. of bright-red blood from the rectum and followed by collapse. Rectal bleeding continued for 4 or 5 days, after which it subsided and the patient improved slightly, although her condition was considered too grave throughout this period to warrant ileostomy and cecostomy.

At about this time, a psychiatric consultation was first requested. The patient had been depressed and had talked of suicide; the history showed that her father had committed suicide the preceding fall, and that she had been very attached to him, and had continued to be disturbed by his loss. According to the history, the mother was a very difficult person, and the patient would not see any member of her family except her sisters. Her condition was too grave to permit any intensive psychotherapeutic procedures, and it was decided to follow her, in the hope that her physical condition might improve sufficiently to permit psychotherapy. Her condition, however, continued to grow worse. The patient was given a high-protein, high-calorie diet, with concentrated vitamin products, feeding being given by nasal tube because it was refused by mouth. She complained of abdominal

\*I am indebted to Dr. Rustin McIntosh for permission to include this case report.

pain, and an opiate was resorted to freely. She began to run a markedly elevated axillary temperature, between 102 and 103°F. The condition became graver, and diarrhea continued unabated, the stools being thin and slimy, and numbering between sixteen and twenty-five a day. The entire perianal area became red and erythematous. The patient gradually failed and expired on September 29. Permission for autopsy was obtained, and the typical picture of a chronic ulcerative colitis, with perforation of the colon at one place, was found. The heart showed fresh rheumatic lesions, but these were not considered extensive enough to have contributed to her death.

The final note in the child's chart stated that she had died on the first anniversary of her father's suicide; which was also her mother's birthday. Subsequent check of the father's death certificate showed that she had not died on the exact date, but within a week of this anniversary. It is of interest that this mistake, apparently obtained from some member of the family, should have crept in; and although it might have made the story more striking had she died on the anniversary, there is good reason to believe that the case actually represented one of indirect suicide.

### DISCUSSION

Except for basic factors relating emotions to disturbances of the large bowel, the psychophysiologic mechanism of ulcerative colitis is not yet understood. Sullivan<sup>9</sup> raised the question of whether stimulation of centers in the diencephalon, due to emotional stress, and the whipping up thereby of peristalsis in the small intestine may not lead to the emptying of abrasive digestive juices into the large bowel, or whether the enzymes may not be more potent or the mucosa less resistant in such cases. There is, in any event, a surface digestion of the mucosa that makes bacterial invasion easier, and ulceration results. Because of the patient's inability to solve his problems, hypermotility of the intestine persists, with constant irritation and chronic colitis.

Findings in mucous and spastic colitis may eventually help in elucidating the mechanism. White, Cobb and Jones<sup>13</sup> have recently published a monograph on this subject. The question whether ulcerative colitis represents a more advanced form of mucous or spastic colitis has been raised from time to time. Buzzard, Richardson and Turner<sup>4</sup> state that mucous colitis did not precede the development of ulcerative colitis in any of their 116 cases. Cullinan,<sup>14</sup> Spriggs<sup>3</sup> and others have had experience similar to that at the Presbyterian Hospital. However, certain personality factors and mechanisms do show a marked similarity, bearing out Murray's original conjecture. If spastic colitis and ulcerative colitis are in large measure the result of personality factors and conflicts, one would expect certain similarities since the organ affected is the same, although the deciding determinants

might be sufficiently different to make it rare for both disorders to appear in the same person.

The most interesting personality factors in relation to spastic colitis have been worked out by Alexander<sup>15, 16</sup> and his group at the Chicago Psychoanalytic Institute. Unfortunately, space does not allow a discussion of this interesting subject except to say that, in contrast to the gastric, peptic-ulcer type, he found that the cases of spastic colitis do not stand responsibility well, or if they do during good health, they indulge their dependence to a marked degree when ill. The Yale investigators<sup>17</sup> have made the same observation on cases of ulcerative colitis, and have dubbed this group the "giver-uppers." Alexander stressed the symbolic use of feces under some circumstances as a gift, in others as an expression of hostility, based on varying developmental regressions. In connection with the use of feces for hostile purposes, he calls attention to the use of offensive substances for defensive purposes, as in the skunk. Feces as the symbolic equivalent of a baby was clear in one case, a confusion that seems to have been present in one of my series.<sup>11</sup>

Much could be said of the relation of personality to disease of the colon. Alexander compares the gastric type with the phobic, and the colonic type with the compulsive neurotic. Both reactions occur in ulcerative colitis, the compulsive reaction being by far the more prominent. My impression is that the difference lies in the more narcissistic organization of the personalities in ulcerative colitis, with the underlying reaction more a psychotic than a psychoneurotic one. In some cases, the symptoms mask a severe depression. Perhaps the recurrent character of the disorder is significant in this regard. In several cases, the disease seemed definitely a type of organic suicide. This conclusion was also independently arrived at by the Yale group.<sup>17</sup> It is premature to make definite pronouncements on the character of the underlying neurosis, because this factor apparently differs. I believe, however, that in many cases there is a direct relation between the severity of the physical reaction and the underlying psychopathology. Psychoneuroses rarely cause death; psychoses frequently do.

### SUMMARY

A survey of the literature on the psychiatric aspects of ulcerative colitis shows that certain characteristics are commonly found in patients suffering from the disease. They are apt to have a fixation on some member of the family, usually the mother, and conflict develops in situations threatening this dependence, especially engagement and

barium enema showed advanced ulcerative colitis. X-ray study revealed small areas of translucency in the tip of the gall bladder, indicating calculi, but with normal physiologic functions.

During the 10 weeks in the hospital, the case was considered interesting because of its chronicity without any demonstration of marked anemia or evidence of chronic disease on inspection. There was no relief from bismuth, diet or rest in bed. The patient was given a series of four autotransfusions, with radiation of the blood by ultraviolet light. These did not result in any improvement, and she was discharged to the Out-Patient Department, where she was followed.

Information obtained 6 months later showed that the patient had been unable to become pregnant during the first 14 years of marriage. A year and a half before her pregnancy, she had taken treatment for sterility, and at about the same time she acquired a lover, since her husband had proved sexually unsatisfactory to her. She was convinced that her first child had come from this union. She had been unable to believe that she was pregnant for some time, but when convinced of it she had been of two minds. One was joy at the idea of having a child, and the other was conflict and conscience over its paternity. This conflict came to a climax after the child's birth, and was increased by doubts whether it would live. The child did live, and is now perfectly healthy. Its coming had been a considerable source of interest to friends and neighbors on account of the patient's 14 years of barrenness. Her husband had likewise been pleased, and never suspected that the child was not his. The patient stated that she had never told anybody about the situation, not even her sister, but that *not a single day had passed without its being on her mind.*

The patient was certain that her husband was responsible for the second pregnancy, which occurred after 6 months. She was not clear why she had this child except that she took no precautions. She considered the interval between the pregnancies too short, and was resentful because she had had no rest from the first.

The patient did not improve dramatically following this revelation, but did seem considerably relieved in her mind. She continued to hold her own, was able to do her housework, and had brief periods of normal stools. Her lover died about a year after her discharge from the hospital. The environmental situation held little hope of improvement, and further psychotherapy did not seem to be the answer to the problem. The patient was referred to Dr. Thomas T. Mackie's service at the Roosevelt Hospital, New York City, and a report from that hospital stated that during the following year her course had been one of slight improvement, with minor periodic exacerbations. No infective agent was revealed.

CASE 3.\* L. B., an 11-year-old girl, was admitted to the Babies Hospital, New York City, in July, 1937, because of chorea and diarrhea. One sister was reported to have had intermittent attacks of diarrhea, with blood-streaked stools, for the previous 2 years. In March, the patient had begun to have intermittent attacks of loose stools, with some lower abdominal pain. About June 1, the mother had noticed rectal bleeding, with flecks of blood in the stools. A private physician had advised admission to another hospital, where x-ray studies of the colon were negative. During the 2nd day of her stay in this hospital, the patient had developed generalized choreiform movements. She had been removed from this hospital and

given three injections of triple typhoid vaccine at home. The chorea had progressed for the 10 days prior to admission to the Babies Hospital, and the child had become unmanageable at home.

Physical examination showed an asthenic, undernourished child who was thrashing about the bed with violent choreiform movements involving the entire body. On the skin about the angles of the mouth were patchy, vesicular, somewhat encrusted fissures, spreading inside the mouth and involving the buccal mucosa and the mucous membranes beneath the tongue, where there was an irregular, dirty, ulcerated lesion about 1 by 2 cm. The heart was not enlarged. A soft apical systolic murmur was present. The abdomen was scaphoid. The liver edge was palpable just at the costal margin. The spleen was not palpated. There were no gross neurologic changes. The temperature was 100.2°F., the pulse 120, the respirations 18, and the blood pressure 105/70.

The blood showed a red-cell count of 3,000,000 with a hemoglobin of 56 per cent, and a white-cell count of 18,150 with 77 per cent polymorphonuclears and 21 per cent lymphocytes. Subsequently, after gross hemorrhages, the red-cell count dropped to 1,500,000 with a hemoglobin of 28 per cent. The urine showed a faint trace of albumin, with much sediment and debris and granular casts. The stools were negative for pathogenic organisms. A smear of the mouth ulceration revealed no Vincent's organisms. Stool examinations frequently showed occult blood, but no ova or parasites.

On sedation with Chlorotone over a 2-week period, the choreiform movements entirely subsided, but the diarrhea continued unabated, with nine to eighteen stools a day. Proctoscopic examination showed granular rectal and sigmoid mucosa, with multiple points of bleeding but no large ulcerated areas. Because of rapidly developing anemia, the patient was given a series of citrated transfusions, with some rise in the red-cell count and hemoglobin. She was placed on a high-carbohydrate diet and given concentrated vitamin preparations, both by mouth and parenterally. Two weeks after admission, she became maniacal, thrashed about the bed and was uncontrollable. A neurologic consultant attributed the behavior to Chlorotone poisoning, and the drug was discontinued; the maniacal symptoms disappeared, and no further choreiform movements were noted. One month after admission, the patient had several large massive hemorrhages, amounting to between 300 and 500 cc. of bright-red blood from the rectum and followed by collapse. Rectal bleeding continued for 4 or 5 days, after which it subsided and the patient improved slightly, although her condition was considered too grave throughout this period to warrant ileostomy and cecostomy.

At about this time, a psychiatric consultation was first requested. The patient had been depressed and had talked of suicide; the history showed that her father had committed suicide the preceding fall, and that she had been very attached to him, and had continued to be disturbed by his loss. According to the history, the mother was a very difficult person, and the patient would not see any member of her family except her sisters. Her condition was too grave to permit any intensive psychotherapeutic procedures, and it was decided to follow her, in the hope that her physical condition might improve sufficiently to permit psychotherapy. Her condition, however, continued to grow worse. The patient was given a high-protein, high-calorie diet, with concentrated vitamin products, feeding being given by nasal tube because it was refused by mouth. She complained of abdominal

these patients will be symptom-free carriers and hence will constitute a serious public-health menace.

Laboratory experiments have demonstrated that some micro-organisms, among which is the gonococcus, develop a sulfonamide fastness that is retained by many subsequent generations and causes the organisms to lose none of their characteristics. It has also been shown that gonococci that have been made resistant to sulfanilamide are also resistant to sulfapyridine. It is not yet known whether these laboratory experiments have any clinical significance.

The mere fact that a patient with a gonococcal infection obtains a cure after having been treated with a sulfonamide does not justify accrediting the cure to chemotherapy. As a matter of fact, if given sufficient time during which the body defenses are permitted to function, most patients recover from gonorrhea regardless of the type of treatment. Therefore, time must be taken into account when one attempts to evaluate any plan of treatment. There is general agreement among those who have worked with the sulfonamides that if they are to be effective there will be evidences of clinical response within a very few days, and cases that do not show a response within five days will usually not be benefited by chemotherapy, no matter how long it is continued.

In an analysis of the reports of a large number of patients who had been treated in the Genitourinary Clinic of the Boston Dispensary in the presulfonamide days, it was found that no patient had been cured by local treatment within two weeks. It therefore seemed justifiable to credit cure to chemotherapy if the use of one of these compounds resulted in cure within two weeks. Approximately 1500 case histories of patients who have been treated with chemotherapy are available but, because eight different compounds have been used, no one group is yet large enough to warrant accepting the findings as conclusive. The appraisal studies excluded patients who had had their infection for more than one week before coming to the clinic or who had any previous treatment, and also those who did not remain under observation long enough for an adequate bacteriologic study after they became symptom free.

The results with sulfanilamide and sulfapyridine, which were reported in a previous communication,<sup>2</sup> were as follows. In the group treated with sulfanilamide, 48 per cent were classified as clinical failures, and 23 per cent more as bacteriologic failures—a cure rate of 29 per cent. And in the group treated with sulfapyridine, 5 per cent

were classified as clinical failures and 40 per cent more as bacteriologic failures—a cure rate of 55 per cent. All cases that remained clinically active for two weeks were classified as clinical failures, and those that became symptom free within two weeks and subsequently had one or more positive cultures were classified as bacteriologic failures. No serious reactions were noted in any patients treated with sulfanilamide or sulfapyridine. However, a large number of patients who were treated with sulfanilamide complained of dizziness and lassitude, and 40 per cent of those treated with sulfapyridine complained of gastrointestinal symptoms. These mild toxic reactions caused many patients to discontinue the drug against advice. In about half of each group, a drop of 30 to 50 per cent was noted in the white-cell count.

Four hundred and forty cases of gonococcal infection in men have been treated at the Boston Dispensary with sulfathiazole, but only 265 of these comply with our evaluation standards: that is, entrance to the clinic during the first week of infection with no previous treatment, and observation for a sufficient length of time to carry out a series of cultural studies. Of the 265 cases, 41 (15 per cent) were clinically active at the end of the second week, and in addition 26 (10 per cent) became asymptomatic within two weeks but had one or more positive cultures between the first and eighth weeks after becoming symptom free. The remaining 75 per cent represents the cure rate that can definitely be attributed to sulfathiazole.

There was no significant difference in the cure rates of those cases that had and those that did not have local treatment. Except for its alleged case-holding properties, there is no indication for local treatment in the cases that respond to sulfathiazole. Toxic symptoms were almost entirely absent, and none were serious enough to cause the patient to discontinue the drug. However, since drug fever, rash, headache, nausea and kidney complications have been reported by other investigators, it should not be concluded that sulfathiazole is entirely without toxic possibilities.

In this series, there were no blood changes other than an occasional insignificant drop in the white-cell count. The combined sulfathiazole in the blood stream varied from 0.5 to 6.0 mg. per 100 cc., and there was no correlation between the blood concentration and clinical response. Some of the failures showed the highest concentration.

Last year, the pooled case reports of patients treated with sulfanilamide from five clinics in different sections of the country were analyzed and reported by Pelouze et al.<sup>3</sup> That study showed a 30 per cent cure rate with sulfanilamide. The

same group is now studying the efficiency of sulfathiazole, and the results will be reported next June. From the available figures, it appears that the report will credit sulfathiazole with a cure rate of approximately 70 per cent and an asymptomatic carrier rate of from 5 to 6 per cent.

Another group<sup>4</sup> has, since December, 1940, been conducting a rapid appraisal of chemotherapy in gonorrhea in men. An average of 100 reports a week are being sent to a central tabulating unit for statistical analysis. Although this study has not been completed, 77 per cent of the patients treated with sulfathiazole are becoming symptom free within two weeks, compared with 40 per cent of those treated with sulfanilamide. Positive laboratory tests are being reported in only 3 per cent of the patients who have been symptom free for fourteen days.

These studies correspond with the experience at the Boston Dispensary—that is, they show the definite superiority of sulfathiazole to sulfanilamide in bringing about an early clinical response. The difference between the percentages of the bacteriologic failures in the three groups can be accounted for by the fact that most of the positive cultures in the Boston Dispensary group were obtained during the first two weeks after the patients became symptom free, whereas the positive cultures in the other two groups were obtained after the patients had been symptom free for two weeks.

The few cases that do not respond to chemotherapy still present a therapeutic problem. A small number of cases respond to a second course of sulfathiazole given ten to fourteen days after the first course, but no infection responds to a third course. Many patients who are not cured by sulfanilamide or sulfapyridine become symptom free soon after sulfathiazole treatment is started, but no patients in whom sulfathiazole fails respond to either sulfanilamide or sulfapyridine. Some form of local treatment is the best one can offer in cases in which the sulfonamides are unsuccessful. In men, potassium permanganate

irrigations, hand injections of one of the silver salts, and moderately skillful prostatic massage, when indicated, result in cure of most of these gonococcal infections.

A factor that makes the evaluation of any treatment of gonorrhea extremely difficult and is partly responsible for the variation in the figures reported by different clinics is the high lapse rate, which in some cases is 100 per cent. The lapses from treatment at the Boston Dispensary are about equally divided among cases that were clinically active and those that were inactive at the time of the last clinic visit. It is not known whether the patients in the former group lapsed because they became symptom free before the time of the next expected visit, or because they did not and consequently went elsewhere for treatment. If there were an opportunity of carrying out adequate bacteriologic studies in the patients who lapsed after they became asymptomatic, the figures would be more significant.

Present methods of treatment could be improved if more were known about the biology of the gonococcus, man's defense mechanism to gonococcal infection, and the mode of action of the sulfonamides. Because many outstanding scientists are devoting considerable time to these problems and are constantly adding information, sulfonamide failures may soon be extremely rare. Gonorrhea would then be a much less important disease than it has been throughout the ages, because destructive complications, the result of uncontrolled infections, would be almost nonexistent.

## RECENT ADVANCES WITH CHEMOTHERAPY IN THE TREATMENT OF INFECTIONS OF THE URINARY TRACT\*

EDWARD N COOK, MD†

ROCHESTER, MINNESOTA

**S**URVEYING the advances made in the field of chemotherapy in the past decade, those who are primarily interested in urology cannot but be proud of the contributions made by the workers in this specialty. In 1931, Clark<sup>1</sup> and Helmholz<sup>2</sup> first demonstrated a scientific approach to the treatment of infections of the urinary tract. It is true that their chemotherapeutic agent was synthesized in the body by a prescribed diet, but their work immediately prompted many others to attempt the sterilization of urine in the body by administering various chemicals orally or intravenously. Rosenheim<sup>3</sup> reported the results of his work with mandelic acid, and one of the first and finest chemotherapeutic agents came into wide use; this drug, it is true, has a limited use, and certain very definite conditions must be satisfied if it is to be effective. A few years later, the advent of the sulfonamide compounds was heralded with great acclaim, and this group of drugs has been of great aid in cases in which the administration of mandelic acid has not been satisfactory.

Because sulfanilamide is very reactive chemically, a multitude of derivatives have been synthesized, many of which have proved to be of even greater value than the parent substance in the treatment of certain types of disease.

A discussion of all these compounds is impossible. This paper therefore reviews briefly the experimental and clinical data on mandelic acid, sulfanilamide (*p*-aminobenzenesulfonamide), azo sulfamide (disodium 4 sulfamido phenyl-2-azo-7-acetyl amino-1-hydroxy naphthalene 3, 6-disulfonate), sulfapyridine (2-sulfanil aminopyridine) and sulfathiazole (2-sulfanilamidothiazole).

## MANDELIC ACID

Perhaps the most thorough experimental work in testing the efficacy of these various compounds against the organisms usually found in the urinary tract has been done by Helmholz. Soon after the publication of Rosenheim's report on mandelic acid, Helmholz<sup>4</sup> presented the results of his studies *in vitro*. To be effective, the drug must be present

in the urine in a concentration of at least 0.5 per cent, and the pH of the urine must not be greater than 5.5. By using varying concentrations of the drug in specimens of urine in which the pH varied, he was able to show that the usual gram negative bacilli are rather easily killed at the concentration of mandelic acid and at the pH mentioned previously. *Streptococcus faecalis* can also be destroyed when these conditions are satisfied, however, other streptococci, staphylococci and micrococci are not destroyed.

It is thus clear that a general grouping of the infecting organism is necessary before this drug is used as a chemotherapeutic agent. Cultures are not necessary, but helpful. Gram's stain suffices in most cases to demonstrate the presence of gram negative bacilli or *Strep. faecalis*. When the use of mandelic acid has been decided on, one essential condition must be satisfied, that is, renal function must be normal. At the Mayo Clinic, some untoward reactions have been observed when this drug was administered in cases in which the blood concentration of urea was higher than 40 to 50 mg per 100 cc.

The importance of an adequate dose and of the limitation of fluids during the use of mandelic acid is well known. If the urine cannot be sterilized in eight to ten days, it is advisable to discontinue the drug and administer it again after a rest period of one week. Provided the desired concentration can be obtained in the urine, and an adequate pH maintained, the urine should become sterile. If it does not, there undoubtedly is some complicating urologic lesion.

## SULFONAMIDES

I have been impressed with the progress that has been made with the sulfonamide group of compounds in the field of therapeutics. Their history, chemistry and pharmacology cannot be discussed here. There is no satisfactory explanation for the mode of action of these drugs. One cannot help believing that the drug has a direct action on the organism itself, or that it acts through an intermediary substance as yet not definitely known. Any effect produced through the immune processes of the body remains to be proved; at present, there are no experimental data that definitely reveal any real stimulation of phago-

†His reactor in urology, Mayo Foundation.

easy to administer the equivalent of more than 100 gr. (6.6 gm.) of the drug daily to a patient by this method. Sulfapyridine and sulfathiazole may be given intravenously in the form of the sodium salts when desired, but this is rarely necessary. Occasionally, an 0.8 per cent solution of sulfanilamide for a continuous irrigation may be used in certain cases of severe cystitis, particularly when incrustations are present.

### Toxic Manifestations

There is no question that the sulfonamide compounds should never be given without close observation of the patient. These drugs should never be given unless the patient can be seen in twenty-four to forty-eight hours; many of the more serious reactions occasionally noticed may thus be averted. However, no serious difficulty is usually encountered in administering these drugs to urologic patients. This is undoubtedly because the dose we use is relatively much smaller than that generally used. I do not consider determinations of the concentration of these compounds in the blood necessary in the proper handling of patients suffering from infections of the urinary tract.

It is not necessary to describe in any detail the many signs and symptoms of toxicity that follow the administration of the sulfonamides. However, the value of close observation in cases of urinary infection should be re-emphasized. By such observation, many of these untoward reactions can be averted when they are incipient. Generally, one can say that azosulfamide is less toxic than sulfanilamide and its more closely related derivatives. Although sulfapyridine produces considerable nausea, sulfathiazole usually produces a mild nausea for the first day or two, but this disappears later. This drug is tolerated by a larger number of patients than any other sulfonamide compound. During its administration in the dose we have used, we have seen gross hematuria in only two or three cases, and microscopic hematuria infrequently. This is usually attended with the finding of sulfathiazole crystals in the urine. In no case, however, have we observed renal colic or anuria.

### SUMMARY

The sulfonamide compounds have contributed greatly to the treatment of infections of the urinary tract. It is essential to study the particular organism and the coexisting lesions present in each case. If therapy is not successful, the patient is entitled to a complete urologic investigation before further therapeutic measures are employed. The required dose in the treatment of infections

of the urinary tract is much lower than that needed in the general field. Untoward reactions are not usual because of the reduced dose; however, close observation is necessary to avert these reactions.

### DISCUSSION OF DR. COX'S AND DR. COOK'S PAPERS

DR. CHAMP LYONS (Boston): Dr. Cook's paper has emphasized one or two things that were summarized by Dr. Cox. The perfect urinary antiseptic has not been found. Mandelic acid, under certain circumstances, has very definite advantages. It should not be completely abandoned, and yet there are cases of urinary infection in which one does not wish to concentrate the urine to the point that is necessary for the successful use of mandelic acid therapy, or in which the kidney is unable to establish a pH consistent with the most efficient working of the drug. Under such circumstances, one resorts to the various other compounds. It is interesting that sulfathiazole seems to be the most widely effective drug, and that it is not necessary to use it in concentrations recommended for the treatment of pneumonia. Adherence to that principle will undoubtedly save grief, but sulfathiazole given for five to nine days or longer carries with it a real risk of setting up some of the toxic side reactions that are so undesirable. Even on the dosage recommended for the treatment of gonorrhea, I have seen granulocytosis.

I still think that a frequent white-cell count is imperative, since one must look out particularly for signs of toxic hepatitis. In dealing with surgical patients who have open wounds and who are receiving sulfathiazole, one should routinely determine the prothrombin level of the blood on about the fourth or fifth day, because bleeding of such wounds is associated with fairly early evidence of toxic hepatitis.

In patients with restricted biliary output, the administration of small amounts of sulfathiazole increases the biliary output, again a hepatotoxic manifestation.

The work of Lilly and others, recently published in the *United States Public Health Reports*, has emphasized the significance of diet in relation to the development of toxic symptoms. Rats fed on a low-protein diet deficient in methionine and cysteine showed a much greater incidence of toxic manifestation. Many of the patients coming under urologic care have by force been restricted in their dietary intake. The way is paved for the development of toxic symptoms.

The one point that I wish to emphasize is that, regardless of the dose, the period from the fifth to the ninth day

of therapy is beset with difficulties in the way of development of toxic symptoms.

In surgical cases an effort is made to conduct operative intervention in association with chemotherapy within the relatively safe period,—before the fifth day,—so that if chemotherapy must be discontinued because of the onset of toxic symptoms the surgical part of the procedure and the time of possible flare up of the recent infection will have elapsed.

DR CHESTER S. KEEFER (Boston) My interest in urinary tract infections began some years ago with the study of colon bacillus bacteremias, and since that time a large number of chemotherapeutic agents have been introduced except for a few changes the general principles of the treatment of urinary tract infections have remained essentially unaltered.

No case has been completely studied, in my opinion unless the specific infective agent has been isolated and until the underlying anatomic lesion that is responsible for this infection has been recognized.

The first of these two principles can usually be carried out without much difficulty, provided a good bacteriologic study is made. One cannot distinguish sufficiently between the various gram negative and gram positive organisms by the simple gram stain.

The second point is that the anatomic lesions that underlie urinary tract infections can usually be recognized by careful and expert study. The most serious lesion that predisposes to urinary tract infection is, of course, some type of obstruction. I hesitate to mention that to a group such as this since it is a commonplace but unless obstructive lesions are relieved many disappointing results occur in the use of chemotherapeutic agents.

Besides the relief of obstructions, other factors enter into the prognosis in urinary tract infections: the age of the patient, the presence or absence of bacteremia, the type of infecting organism and the type of complication as mentioned by Dr Cook.

Colon bacillus infections usually are particularly stubborn in patients with diabetes. Furthermore, patients who have thrombophlebitis of small intrarenal veins do not respond to chemotherapeutic agents. In most cases such patients respond only to nephrectomy and one may suspect such a condition if there are chills and fever with bacteremia but without pus, or if an operation on the genitourinary tract has been performed.

There may also be a very poor outlook in cases of ureteral obstruction that cannot be relieved by the usual simple operative procedures. One must accordingly take these facts into consideration in planning treatment.

During the past year at the Massachusetts Memorial Hospitals sulfathiazole has been used almost exclusively because *in vitro* experiments, as well as studies of patients, have shown that this drug is more effective than sulfanilamide in the treatment of many infectious agents in addition the concentration of urine that is effective may not need to be so high as that with sulfanilamide. The question of the optimal concentration in the urine has, of course, excited considerable interest.

Dr Cook reported the work of Halmholz who discovered that a level of 30 mg per 100 cc caused marked inhibition. Of course one can produce effective inhibition with 30 mg per 100 cc in the urine provided that the inoculum is small; this is a significant point in interpreting any *in vitro* experiment. On the other hand with a very large inoculum and a great deal of concentration it is often very difficult to show any stasis of growth.

Dr Lyons properly emphasized a significant fact in the giving of the sulfonamide drugs—the reaction of the urine need not be taken into account. Some of the conflicting

opinions concerning the variation in the activity of these drugs with the reaction are due to the fact that the inoculum, the number of organisms and the amount of drug used in the experiments have not been properly assessed.

The concentration in the urine is of the utmost importance. A relatively high concentration can be obtained with relatively small doses by mouth. If 15 gm of sulfathiazole is given in a 24 hour period and if the urinary output is limited to 1500 cc there will usually be a concentration of about 100 mg per 100 cc, this is generally sufficient to take care of the average case of urinary tract infection provided that the infection is not too heavy.

Finally I should again like to stress the fact that one does not need to pay attention to the reaction of the urine in most of these cases and that if one is unable to demonstrate a positive effect one should attempt to relieve obstructive lesions.

DR GEORGE G. SMITH (Boston) I was much interested when Dr Cook said about the use of mandelic acid in staphylococcus infections. I realize that his statements are based on *in vitro* experiments. The trouble with mandelic acid *in vitro* seems to be that one cannot reach the pH of the urine below 7.0.

A complication of sulfathiazole therapy that I happened to observe, although it may not be particularly new, might be worth mentioning. A sixty year old woman who was being treated by a surgeon for a septic sinus from an old encephalitis received 4 gm of sulfathiazole daily for five days. The fluid intake was not regulated. The patient was probably given very little fluid. At the end of five days she developed complete anuria and the nonprotein nitrogen rose very rapidly. At the surgeon's request I cystoscoped her. The bladder was normal and contained no urine. Sticking out of the left ureter was a small white speckle. The right ureter looked normal but, when I attempted to insert a catheter into it, proved to be obstructed. I prodded it with the catheter, and a great deal of muddy material was discharged after which I was able to get the catheter to the kidney. On the left side the catheter went more easily. I left these catheters in overnight and 90 ounces of urine drained. The patient made a rapid recovery so far as the kidney condition was concerned. In this case the sulfathiazole had crystallized in the urine and had obstructed the ureter. Dr Deming has reported similar cases with sulfapyridine.

DR RICHARD CHUTE (Boston) I should like to hear of experiences with the use of an 0.8 per cent solution of sulfanilamide as an irrigant. Possibly, Dr Quinby has some information. I know of several patients with postcatheterization cystitis—not my own—who have been treated and cured by local washes of sulfanilamide solution without any oral therapy, and I wonder if anyone has had similar experiences that would enrich the general knowledge.

DR WILLIAM C. QUINBY (Boston) The work to which Dr Chute refers concerns the use of a solution of sulfanilamide to irrigate the renal pelvis in cases in which for one reason or another, reactions to the solution by mouth occurred. In a few cases very definite relief was obtained by irrigation of the renal pelvis with such a solution and definite absorption can be demonstrated by examination of the blood after such an irrigation. I do not believe that we have had more than a case or two in the last year. Most of the patients were diabetic and therefore poorly resistant to infection or for some reason or other,—because of an alarming blood picture or because of fever,—it was considered unsafe to continue irrigation of sulfanilamide.

## TRAUMATIC OBSTRUCTION OF A MAIN BRONCHUS\*

## Report of a Case

M. DAWSON TYSON, M.D.,† AND JOHN S. LYLE, M.D.‡

HANOVER, NEW HAMPSHIRE

**A**N injury of the chest wall, with crushing or actual section of the main bronchus, is a rare occurrence and is nearly always fatal. We have found in the literature case histories of 8 patients who survived such an injury, with resultant complete bronchial obstruction.<sup>1-6</sup> In these cases, the force producing the injury was regularly of a very severe degree, such as that caused by a truck or car passing over the thorax or by a heavy weight falling upon the chest. In some, there were numerous rib fractures; in others, there was no evidence of bone injury. The ages varied from three years to thirty-three years at the time of the accident. All the patients were in extremely critical condition immediately after the injury. In all but 1 case, convalescence was prolonged.<sup>2</sup> After recovery, 6 of the 8 patients returned to normal life. One other, reported by Krinitzki,<sup>1</sup> had remittent pain on the affected side, and seven years later developed tuberculosis of the uninjured lung. The remaining patient, reported by Supino,<sup>5</sup> had severe dyspnea and continual pain on the injured side; death occurred in ten years, and was apparently a direct result of the injury.

The left main bronchus was injured in 5 cases, and the right main bronchus received the damage in the other 3. Three patients came to autopsy between ten and twenty years after injury, and 2 underwent exploratory thoracotomies twenty and thirty years later (Rienhoff<sup>3</sup>). In these 5 cases, it was observed that the lung was shrunk to the size of a fist, was of leathery consistence, and occupied the upper posterior portion of the corresponding hemithorax. It was Rienhoff's opinion that in his 2 operative cases, the pulmonary arteries, as well as the bronchus, were occluded. In the autopsied cases, section of the atelectatic lung revealed that the bronchial tree was filled with a jellylike mucus, and the whole organ presented the picture of "drowned lung," familiar to thoracic surgeons. In Krinitzki's<sup>1</sup> case, the patient died of a tuberculous infection of the remaining lung, which started seven years after the injury. It is noteworthy that no tuberculous involvement of the atelectatic lung was found.

Compensatory changes take place in almost the same manner as in patients who have sustained a

total pneumonectomy, namely by increase in the size of the remaining lung, shift of the mediastinum toward the involved side, elevation of the diaphragm and contracture of the hemithorax on the side of the injury. It is interesting to note that chest pain and dyspnea have been described in several cases during the period of intrathoracic readjustment; this aspect is discussed later. Infection of the injured lung has apparently not taken place.

Treatment has varied in the different cases, but the chief methods employed consist in supportive measures at the time of injury, with oxygen administration for relief of dyspnea and cyanosis. Aspiration of air from the pleural cavity was performed in some cases. Jones and Vinson<sup>4</sup> report incision above the sternal notch for relief of mediastinal emphysema. Rienhoff's patients complained of pain in the chest on the injured side twenty and thirty years after the injury; exploratory thoracotomy, with release of pleuropericardial adhesions, gave relief in both cases. Four months after injury, Clerf<sup>6</sup> instituted pneumothorax on the injured side in 1 case and obtained relief of dyspnea on exertion.

The following case exhibited findings that led to a diagnosis of traumatic rupture of the left main bronchus, with complete occlusion.

## CASE REPORT

A 26-year-old man, with a chief complaint of weight loss, pain in the chest and dyspnea, was admitted to the Mary Hitchcock Memorial Hospital on December 4, 1938. He had been injured in an automobile accident during the preceding August and had been taken to a nearby hospital in a critical condition. A letter from his physician stated that at the time of the injury the patient coughed up bright-red blood. He was unconscious and cyanotic on arrival at the neighborhood hospital. Shortly after admission there, the temperature rose to 104.8°F., and the pulse reached 160. Supportive measures were employed, although their exact nature was not revealed. Improvement was very slow, and the patient left the hospital against advice on September 4, 1938, with a fracture of the left scapula, according to the statement of his physician.

At the Mary Hitchcock Memorial Hospital, it was found that the excursion of the left thorax was diminished. There were dullness to percussion and absent breath sounds over the left chest in the upper anterior and posterior aspects. The cardiac impulse was in the fourth interspace 16.5 cm. to the left of the midsternal line, and the trachea could be felt to the left of the midline. The vital capacity was 54 per cent of normal. Overexposed x-ray films showed that the whole trachea was deviated

\*From the Mary Hitchcock Memorial Hospital, Hanover, New Hampshire.

†Staff surgeon, Mary Hitchcock Memorial Hospital.

‡Assistant in thoracic surgery, Mary Hitchcock Memorial Hospital.

markedly to the left (Fig. 1). The left lung apparently occupied the upper portion of the left hemithorax, and the heart was displaced into the left chest. The diaphragm was elevated, and the intercostal spaces were narrowed. The right lung extended into the left chest,

compensatory changes had had time to take place. He was readmitted on January 31, 1939, feeling better and having gained 12 pounds. He still had dyspnea, however, and some pain in the left chest. The vital capacity was 47 per cent. The cardiac impulse was in the third interspace

FIGURE 1.

occupying about one third of this cavity. Bronchography demonstrated a complete obstruction of the left main bronchus 3 cm. distal to the tracheal bifurcation (Fig. 2). Bronchoscopic examination by Dr. John A. Murtagh demonstrated that the left main bronchus terminated blindly, and biopsy showed that the blind end was lined by normal bronchial mucosa.

The patient was allowed to go home for a month, to see what improvement would occur when further com-

in the axillary line. It was thought that the continued pain and dyspnea might be due to the sudden and marked shift of the mediastinal structures to the left; therefore, a pneumothorax was given in the left pleural cavity in an attempt to correct the mediastinal displacement. The initial inspiratory pressure was -38 cm. of water. Several pneumothorax fillings gave considerable relief of the dyspnea and pain, but this treatment was abandoned because of the development of fluid.

On March 7, the patient was again admitted to the hospital, complaining of a return of dyspnea and chest pain. X-ray examination showed a complete absorption of the intrapleural air and fluid. A series of pneumothorax injections was again performed. The initial inspiratory and expiratory pressures were  $-58$  and  $-44$  cm. of water, re-

In addition to the rarity of the condition, this case presents several points of interest. In the first place, the relief of pain and dyspnea by the use of pneumothorax suggests that the pull of the atelectatic lung was the cause of the symp-

FIGURE 2.

spectively, at the time of the first injection. After several fillings, there was marked relief of chest pain and dyspnea, and the patient finally felt well enough so that the injections were discontinued. After a short stay at home, he was able to return to work and has remained well to date.

He was seen in the Out-Patient Department in February, 1940, when a pneumothorax needle was inserted into each pleural cavity; the pressure readings were  $-6$  and  $-8$  cm. respectively.

The high degree of negative pressure ( $-58$  and  $-44$  cm. on one occasion) certainly indicates that the pull may have been very strong. It is probable that this pull is a large factor in producing the contralateral pulmonary enlargement, although the compensatory changes in this case apparently did not take place rapidly enough to

prevent the formation of excessive negative pressures. It seems likely that the absorption of air from the pleural cavity after total pneumonectomy and the consequent negative pressure may be important factors in producing the compensatory changes in the remaining lung.

The absence of infection in the atelectatic lung is noteworthy in this case as well as in those previously reported. Although the condition of the lung seemed to favor a suppurative process, the fact that the bronchial obstruction was complete probably prevented contamination of the "drowned lung." As supportive evidence of this concept, Lemon<sup>7</sup> found in laboratory animals that a partial bronchial obstruction favored pulmonary infection, whereas infection was not encountered when the obstruction was complete.

The eventual development of emphysema in the remaining lung, because of overstrain of the elastic tissue, is a possibility. Bigger<sup>8</sup> points out that estimation of the intrapleural pressure on the sound side will give an index of the state of pulmonary elasticity. In the case reported, readings were taken on both sides fifteen months after the injury, and the pressures were found to be -6 and -8 cm., which could be considered to be in-

dicative of a normal elastic tone, although the eventual elasticity cannot be foretold. As stated by Bigger, circulatory embarrassment, if present, can be corrected at any time by thoracoplasty, but emphysematous changes are irreversible. It therefore seems logical to resort to thoracoplasty if successive pressure determinations show a dangerous decrease in pulmonary elasticity on the unaffected side.

### SUMMARY

A case of traumatic obstruction of a main bronchus is reported. Cases previously reported in the literature are briefly discussed, and certain physiologic aspects of the condition are considered.

## THE PROTEIN OF THE CEREBROSPINAL FLUID IN PATIENTS WITH CHRONIC ALCOHOLISM\*

ELLSWORTH H. TROWBRIDGE, JR., M.D.,† AND LAZARUS SECUNDA, M.D.‡

BOSTON

COMPARATIVELY few reports have appeared in the literature concerning the elevation of the protein of the cerebrospinal fluid in patients with chronic alcoholism. Because of the significance that is universally attached to the cerebrospinal-fluid protein in evaluating the neurologic status of a patient, more facts on this subject in alcoholic patients are needed. This study was undertaken primarily to establish the incidence of abnormal changes in the protein level in cases of chronic alcoholism of varying duration and severity.

The cerebrospinal fluid was examined in 641 cases of chronic alcoholism admitted to the Boston Psychopathic Hospital between 1929 and 1939. The ages of the patients ranged between sixteen and seventy years, with an average of forty-two years. They were classified as follows: delirium tremens,

129 cases; Korsakow's psychosis, 24 cases; alcoholic auditory hallucinosis, 145 cases; other types of alcoholic psychosis, 163 cases; and chronic alcoholism without psychosis, 180 cases. Six hundred and ten patients (95 per cent) had consumed an average of one pint of whiskey a day for five to thirty years. The remainder had drunk heavily for two to six months prior to entry.

One hundred and fifty-eight nonalcoholic patients with no evidence of organic disease of the nervous system were selected as control cases. The clinical diagnoses in these were as follows: dementia praecox, 83 cases; manic-depressive psychosis, 45 cases; involutional psychosis, 21 cases; psychosis due to metabolic disease, 6 cases; and psychoneurosis, 3 cases. The ages of these patients ranged between eleven and sixty years, with an average of thirty-six years.

The neurologic examination was performed within eighteen hours, and lumbar puncture with-

TABLE 1. *Elevated Total Protein in the Cerebrospinal Fluids of Patients with Chronic Alcoholism and of Control Patients.*

DIAGNOSIS	No. OF CASES	CASES WITH ELEVATED TOTAL PROTEIN				TOTAL
		46-55 MG	56-75 MG	OVER 75 MG		
Chronic alcoholism with psychosis	461	47	35	14		96 (21%)
Delirium tremens	129	9	10	2	21 (17%)	
Korsakow's psychosis	24	2	1	2	5 (20%)	
Auditory hallucinosis	145	21	8	4	33 (23%)	
Other types of psychosis	163	15	16	6	37 (23%)	
Chronic alcoholism without psychosis	180	17	11	4		32 (18%)
Other psychoses (control patients)	158	10	5	0		15 (9%)

greater than 45 mg. per 100 cc. were considered abnormal. The Wassermann reaction of the spinal fluid was negative in all cases. The patients who had signs and symptoms consistent with a known organic disease of the central nervous system not due to alcohol were eliminated from this series. In the 641 cases reviewed, 461 had psychosis and 180 no psychosis.

The protein of the cerebrospinal fluid was elevated (greater than 45 mg. per 100 cc.) in 128 cases (20 per cent) of the total series, whereas in 158 control subjects only 15 (9 per cent) had an abnormal protein content (Table 1). There was little difference in the prevalence of abnormal protein of the cerebrospinal fluid in patients with and those without psychosis, the former group revealing 96 (21 per cent) and the latter 32 cases (18 per cent). The type of psychosis seemed to make little difference. Rosen<sup>2</sup> found in cases of chronic alcoholism with psychosis an abnormal protein in 52 per cent, in contrast with the 21 per cent of our series; Rosenbaum<sup>3</sup> found abnormal protein in 3 per cent of his cases of delirium tremens, in contrast with the 17 per cent of our series.

No correlation exists between the duration and the severity of the alcoholic psychosis on the one hand, and the protein content of the cerebrospinal fluid on the other (Table 2). Furthermore, the number of previous attacks of alcoholic psychosis has little influence on the protein of the cerebrospinal fluid. The patients with a history of one previous attack had protein values between 46 and 88 mg. per 100 cc., and 3 patients who had had 4, 6 and 13 attacks of alcoholic psychosis, respectively, had normal protein.

It might be suggested that the amount of the protein in the cerebrospinal fluid is essentially conditioned by the presence of polyneuritis. We therefore paid attention to the presence of polyneuritis in our cases. The criteria of neuritis were: hypoactive to absent knee or ankle jerks, tenderness or cramps of the calf, hyperesthesia and

had polyneuritis. In only 17 per cent of the cases of polyneuritis was there abnormal protein, where-

as in 21 per cent of the cases of alcoholism without polyneuritis there was an abnormal protein.

#### SUMMARY

Of 641 patients with chronic alcoholism, 20 per cent had a protein of the cerebrospinal fluid greater than 45 mg. per 100 cc.

Abnormal protein of the cerebrospinal fluid was more than twice as frequent in patients with chronic alcoholism as in a series of control patients.

The presence, the duration and the number of previous attacks of an alcoholic psychosis had no influence on the protein of the cerebrospinal fluid.

The presence of polyneuritis has no significance in the production of the abnormal protein of the

cerebrospinal fluid, for a larger percentage of the alcoholic patients without polyneuritis had abnormal protein than patients with polyneuritis.

## MEDICAL PROGRESS

### RENAL-FUNCTION TESTS\*

JOHN H. TALBOTT, M.D.†

BOSTON

#### COMMONLY USED TESTS OF RENAL FUNCTION

SEVERAL tests of renal function are commonly employed in the clinical consideration of kidney disorders. These include the testing of ability to concentrate solids, the measuring of excretion of phenolsulfonphthalein, pyelography after intravenous injection of Diodrast or other iodine compounds, and the determination of nonprotein nitrogen in the serum. Each of the tests is based on one or more recognized duties of the kidneys, which may show evidence of deterioration as a result of functional or morphologic change.

#### Ability to Concentrate Solids

The ability to concentrate solids maximally connotes normal tubular epithelium and is the first function to deteriorate in many renal disorders.<sup>1</sup> The ability to concentrate may be determined following reduction of fluid intake or following the injection of pituitary extract. If a subject with normal kidneys restricts fluids for twelve hours, urine specimens voided subsequently at hourly intervals show a specific gravity of 1.020 or greater. Following abstinence from fluid for thirty-six hours, 1.027 should be reached. The injection of pituitary extract<sup>2</sup> has the advantage that it requires little preparation of the patient. At a convenient time, 0.5 cc. of pituitary extract is administered subcutaneously. Urine samples are collected every half hour for three or more hours. A normal response is a specific gravity of 1.020

or greater. In extensive kidney disease, inability to concentrate above 1.014 is evident by either concentration test. In diabetes insipidus, the kidneys have a normal concentrating ability following the use of pituitary extract, but are unable to concentrate following restriction of fluids overnight.

#### Excretion of Phenolsulfonphthalein

The phenolsulfonphthalein test is a measure of the capacity of the tubular cells to excrete this substance. The procedure gives the most information if the amount of dye excreted is partitioned at frequent intervals rather than collected in one sample two hours after injection.<sup>3, 4</sup> During the first fifteen minutes after intravenous injection of 1.0 cc. of dye, a normal person should be able to excrete at least 25 per cent of the total amount. In advanced renal disease, less than 5 per cent may be excreted during this period.

#### Pyelography

Intravenous pyelography gives qualitative rather than quantitative information regarding renal function; nevertheless, the examination is useful to the internist as well as to the urologist. The various iodine preparations used for pyelography are handled by different renal processes, and if this procedure is interpreted as a renal-function test, it is essential to know which compound is used. Diodrast and Hippuran are excreted largely by tubular activity, whereas Skioidan is excreted largely by glomerular activity. Theoretically, it should be feasible to take advantage of the different paths of excretion, to distinguish between glomerular and tubular damage during the incipient stage of a renal disorder. At later stages, this is usu-

†Associate in medicine, Harvard Medical School, and assistant physician, Massachusetts General Hospital.

ally not possible, since kidneys that cannot concentrate solids to a specific gravity above 1.014 during a concentration test are unable to concentrate iodine compounds sufficiently to be visualized by x-ray examination. Exceptions, however, do occur, and in this clinic, more than a dozen patients have been observed whose kidneys were unable to concentrate solids above 1.014 by carefully controlled clinical tests but were readily visualized by intravenous pyelography. Most of the patients who showed this unorthodox finding were suffering from a renal condition other than Bright's disease. In cases in which it was studied, the urine passed immediately after pyelography had a specific gravity above 1.020. The ability to concentrate, therefore, applied only to substances occurring naturally in the urine and not to foreign substances, such as iodine compounds. Diodrast is relatively nontoxic, and no untoward effects need be anticipated by its use in patients with advanced renal impairment.

#### *Serum Nonprotein Nitrogen*

The concentration of nonprotein nitrogen in the serum should not exceed 35 mg. per 100 cc. in healthy persons. Values greater than this usually indicate gross renal failure. An increase in concentration may appear temporarily in a variety of conditions, either from transient impairment of renal function or from an increased formation of nitrogenous waste products. Knowledge of the concentration of nonprotein nitrogen in the serum has been of inestimable service in clinical medicine, but values should be interpreted only after consideration of related findings and data and after determination of other tests of renal function.

#### PRECISE TESTS OF RENAL FUNCTION

All the tests mentioned above can be performed easily in the clinic, and all yield useful information. They are neither quantitatively precise nor sufficiently accurate, however, to detect small variations from the normal or to detect the early changes of anatomic renal disease. For example, it is quite possible for each of the tests to yield "normal results," yet more precise tests show a deficiency as great as 30 per cent in the amount of blood passing through the kidney or in the amount of glomerular filtrate formed. To obtain information regarding these functions, one must use the procedures that are known as clearance tests.

A little more than ten years ago, the concept of "clearance" was introduced in clinical investigation by Van Slyke and his associates<sup>5</sup>; since then, these tests have served an extremely useful function. Urea clearance and creatinine clearance, which were stud-

ied first, have in recent years been superseded by inulin and Diodrast clearance tests. Urea appears in glomerular filtrate, but a variable amount, depending on diuresis, is reabsorbed by tubular activity. Likewise, creatinine appears in glomerular filtrate, and an additional amount is excreted by the tubular cells. Since the clearance of both substances is an index of combined glomerular and tubular activity, it is understood why they are less attractive than the clearance tests devised and described by Smith,<sup>6-8</sup> which measure specific functions separately. The terms inulin clearance ( $C_I$ ), Diodrast clearance ( $C_D$ ), maximum tubular excretory capacity for Diodrast ( $T_{MD}$ ) and maximum tubular reabsorptive capacity for glucose ( $T_{MG}$ ) are gradually appearing in the medical literature, and before many years have elapsed they may be as readily understood as terms now in use in electrocardiography or in clinical chemistry.

The clearance procedures described by Smith are complicated. Nevertheless, it is hoped that modifications of them for clinical use may be made available before long. The tests as described are performed while the patient is fasting and lying

FIGURE 1. *Essential Features of a Typical Nephron in the Human Kidney.*

in the supine position.<sup>8</sup> A continuous intravenous injection is maintained throughout the test. A soft rubber catheter is retained in the bladder, and

urine is delivered without interruption into a container. It may be desirable to catheterize the ureters for 'split function' in certain subjects. This has been done on several occasions by members of the Urological Service at the Massachusetts General Hospital, and no serious obstacles have been encountered. Nor have any serious side or direct effects been noted as a consequence of the test, whatever technic has been employed. During the last four years, our laboratory has performed several hundred clearance tests, and it can be considered no more formidable a procedure than lumbar puncture or proctoscopy. The four tests may be performed during approximately three hours.

An explanation of the functioning unit of the kidney, the nephron, serves as an introduction to a detailed discussion of the clearance tests. A nephron is shown diagrammatically in Figure 1. This has been modified from Smith.<sup>6</sup> Included are glomerulus, convoluted and collecting tubules and a blood supply. It is assumed that blood from the afferent arteriole enters the glomerulus, continues into the efferent arteriole on leaving the glomerular capillaries and, after the functions of excretion and reabsorption are performed in the capillary network about the convoluted tubules, loses its identity as arterial blood and becomes venous. Approximately two million nephrons comprise the functioning renal tissue of an adult.

#### Inulin Clearance

Inulin clearance ( $C_i$ ) is used synonymously with "rate of formation of glomerular filtrate"<sup>6</sup>. Inulin is a starchlike polymer and, if chemically pure, is an ideal substance for use in determining the rate of formation of glomerular filtrate. Approximately 25 gm is necessary for a single test. Inulin is not metabolized by the body and is excreted by the kidneys if injected intravenously. The path of excretion is exclusively through the glomerular membrane, the tubules neither reabsorb nor excrete the substance. As an example, if the concentration of inulin is 100 mg per 100 cc. of plasma and if 125 mg of inulin is excreted by the kidneys into the bladder per minute, 125 cc of plasma must have participated in the formation of glomerular filtrate to allow this quantity of inulin to be excreted (Fig 2). The amount of inulin cleared by the kidneys and the amount of glomerular filtrate formed per minute are identical. These values are expressed as cubic centimeters of plasma cleared per minute. An average value is 125 cc per minute, and the normal range is between 100 and 150 cc per minute. Values should be corrected to a standard body surface area, and Smith has selected 1.73 square meters as the standard in his studies.

#### Diodrast Clearance

Diodrast clearance ( $C_d$ ) is assumed to measure "effective renal blood flow,"<sup>7</sup> that is, effective so far as formation of urine is concerned. An additional small amount of blood supplies inert structures in the kidney, such as connective tissue, and is not measured by Diodrast clearance. The Diodrast used in the determination is the identical iodine compound employed in intravenous

FIGURE 2 Inulin Clearance

Since the plasma contains 100 mg of inulin per 100 cc and since 125 mg of inulin per minute is excreted in the urine the glomerular filtration is 125 cc of plasma per minute.

pyelography. At low blood concentrations, approximately 10 mg per 100 cc of plasma, all the Diodrast entering the arterioles contiguous to functioning nephrons, is removed before the blood leaves the kidney. A portion is removed by the glomeruli, and the remainder is excreted by the tubules. It makes little difference for the calculation of renal blood flow how the nephron removes the Diodrast; the significant point is that the removal is complete in the venous blood returning from the kidneys. Diodrast, like inulin, is not destroyed by the body, and approximately all the Diodrast in the blood eventually finds its way into the urinary bladder. If the concentration of Diodrast in the plasma is 10 mg per 100 cc and if 7 mg of Diodrast is excreted per minute into the bladder, 700 cc of plasma must

have passed through the kidneys to allow for excretion of this amount of Diodrast (Fig. 3). Renal plasma flow, or  $C_D$ , therefore, is 700 cc. per minute. If whole blood contains 40 per cent cells

FIGURE 3. Diodrast Clearance (Low Plasma Concentration).

Since the plasma contains 1 mg. of Diodrast per 100 cc. and since 7 mg. of Diodrast per minute is excreted in the urine, the renal plasma flow is 700 cc. per minute; and since the plasma constitutes 60 per cent of the blood, the renal whole-blood flow is  $700 \div 0.60 = 1170$  cc. per minute.

and 60 per cent plasma, the effective renal flow of whole blood would be approximately 1200 cc. per minute, which is nearly one third the cardiac output. The average normal renal flow of whole blood is 1200 cc. per minute, the values ranging from 1000 to 1400 cc.

#### Tubular Excretion of Diodrast

$T_{MD}$  is the designation for the maximal capacity of the tubules to excrete Diodrast when a greater quantity is presented to them than they are able to handle.<sup>9</sup> This may be determined if the concentration of Diodrast in the plasma is elevated to 25 mg. per 100 cc. At such levels, not all the Diodrast is extracted from the blood as it is at low plasma levels, and a portion of the Diodrast appears in each of three fluids. The first portion appears in glomerular filtrate at the same concentration as it exists in the plasma. The second portion is excreted into the tubules by the tubular cells. The urinary excretion of Diodrast is com-

posed of these portions. If the total urinary excretion and the amount presumably excreted by glomerular filtration are known, the difference is the amount excreted by tubular epithelium. This constitutes the value,  $T_{MD}$ . The third portion is that left in the blood after the tubular cells have functioned maximally. This portion is disregarded and is not used in the calculation. For example, if the concentration of Diodrast in the plasma is 25 mg. per 100 cc. and the rate of formation of glomerular filtrate is 125 cc. per minute, 30 mg. of Diodrast per minute is excreted through the glomeruli (Fig. 4). If a total of 80 mg. per minute is excreted into the bladder, the difference between the total

FIGURE 4. Diodrast Clearance (High Plasma Concentration).

Since the plasma contains 25 mg. of Diodrast per 100 cc. and since it is assumed that 125 cc. of plasma per minute passes through the glomeruli, the Diodrast excreted by the glomeruli is about 30 mg. per minute; however, since 80 mg. of Diodrast per minute is excreted in the urine, the maximal amount of Diodrast excreted by the tubules is  $80 - 30 = 50$  mg. per minute.

urinary excretion (80 mg.) and the amount present in glomerular filtrate (30 mg.) gives a value of 50 mg. for  $T_{MD}$ , a normal figure.

#### Tubular Reabsorption of Glucose

$T_{MG}$  is an index of the maximal capacity of the tubules to reabsorb a specific substance, glucose, when an excessive amount is presented to them.<sup>9, 10</sup> Thus, while  $T_{MD}$  measures the max-

imum capacity of the tubules to excrete a specific substance, *Tmc* measures their capacity to reabsorb a specific substance. For example, if the concentration of glucose in the plasma is elevated to

FIGURE 5 Glucose Clearance (High Plasma Concentration).

Since the plasma contains 400 mg. of glucose per 100 cc. and since it is assumed that 125 cc. of plasma per minute passes through the glomeruli, the glucose excreted by the glomeruli is 500 mg. per minute, however, since 200 mg. of glucose per minute is excreted in the urine, the maximal amount reabsorbed by the tubules is  $500 - 200 = 300$  mg. per minute.

400 mg. per 100 cc. and the rate of formation of glomerular filtrate is 125 cc. per minute, 500 mg. of glucose will appear in glomerular filtrate per minute (Fig 5). If only 200 mg. per minute appears in the urinary bladder, the difference between the glomerular excretion (500 mg.) and the total excretion (200 mg.) gives a value of 300 mg. for *Tmc*, the maximum amount reabsorbed from the

filtrate by the tubular cells; this is an average figure.

### SUMMARY

Several tests for renal function have been described. The procedures that are convenient to perform in the clinic include the testing of ability to concentrate solids, the measuring of excretion of phenolsulfonphthalein, pyelography after intravenous injection of Diodrast, and the determination of nonprotein nitrogen in the serum.

More exact information regarding the specific functions of the kidney may be derived from the various clearance tests. Inulin clearance and Diodrast clearance at low plasma levels measure rates of glomerular filtration and effective renal blood flow, respectively. Other substances might be employed to measure these functions, and would yield similar values. On the other hand, maximal tubular activity, as measured by the excretion of Diodrast or the reabsorption of glucose, is presumably specific, and with each new substance a different set of values would result. This qualification, however, does not detract from the significance of these determinations. In a subsequent progress report, the use of these methods in recognizing and differentiating various unusual renal disorders will be discussed.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 28051

#### PRESENTATION OF CASE

A twenty-three-year-old freight solicitor was admitted to the hospital because of recurrent attacks of abdominal pain.

In the year preceding admission, he experienced three attacks of approximately similar character. In the last episode, which began a week before entry, the patient noted vague epigastric pain during an afternoon. He then ate a large dinner, and two hours later had severe, cramplike pains in the midabdomen and vomited; the pain subsided gradually, with bed rest and local application of heat. He took no food for the next forty-eight hours because of persistent nausea and vomiting. The bowels remained normal. At this time, he consulted a physician, who because of the presence of an abdominal mass in the right lower quadrant and localized tenderness, advised immediate hospitalization. The temperature and white-cell count were normal. The patient refused to enter the hospital and spent the next few days in an active week end in New York City. During this period, there was no pain or discomfort. When he returned to Boston four days later, he agreed to enter the hospital.

Except for the episodes described, the patient had been well. Two and a half years previously, the left foot was crushed in an automobile accident, requiring amputation below the knee, subsequent revisions of the stump and two nerve-crushing operations. Except for slight paresthesias, he had had no trouble with the stump for the year preceding entry.

On admission, the patient was well developed, with a well-healed amputation stump terminating 15 cm. below the left knee. Examination showed a tender, sausage-shaped mass in the right lower quadrant, beneath McBurney's point. The mass measured about 5 by 2 cm., and could be freely moved medially, during which procedure the pain was referred to the umbilicus. The rest of the examination was negative.

The temperature, pulse, respirations and blood pressure were all normal.

Examination of the blood showed a red-cell count of 4,990,000 with 14.7 gm. hemoglobin, and a white-cell count of 6500 with 62 per cent poly-

morphonuclears. The blood Hinton reaction was negative. The urine was normal.

A barium enema passed readily to the cecum, and entered the terminal ileum. There was a sharply defined, smooth concave pressure defect on the medial aspect of the tip of the cecum at the site of the appendix. This defect was constant, and could not be obliterated. It was not possible to fill the appendix. There was no evidence of mucosal ulceration.

On the second hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. LELAND S. MCKITTRICK: May we see the x-ray films?

DR. JAMES R. LINGLEY: The lesion is seen best in the spot film (Fig. 1). Here is the ileocecal valve, and here the tip of the cecum, so that the

FIGURE 1. Spot Film of Cecum.

mass is in the appendix region. The mass appears to be outside the cecum, and there is no involvement of the mucosa. It does not look like a primary tumor of the cecum, and the deformity is due to pressure rather than to intrinsic involvement.

DR. MCKITTRICK: This patient had three episodes of pain over a period of a year, the last attack occurring a week before admission, when a mass appeared or was found when he was examined, forty-eight hours after the onset of the pain. No elevation in temperature or white-cell

count was associated with this mass. The pain was epigastric or midabdominal.

The history is a little bit difficult to interpret, and possibly we ought not to pay too much attention to it. Obviously, the patient was well enough, at the end of forty-eight hours with a mass in the right lower quadrant, to go to New York and not spend his time sitting around a hotel room. When he returned, he had more soreness—something definite—and therefore entered the hospital. We must assume that these attacks of pain were of short duration. There is little evidence of true inflammatory reaction associated with them, and there was no interference with bowel activity. We have a positive finding of a palpable mass in the right lower quadrant in a situation consistent with the location of the cecum. That mass was moderately tender. It was freely movable medially. It was felt a week following onset of symptoms. The temperature and white-cell count were normal, and there was no anemia. Apparently, whatever this mass was or whatever caused it, it had no effect on his general state, and therefore it is reasonable to assume it was not a progressive thing that had been going on over a period of a year.

We know that the patient had a tumor, and I cannot determine with any accuracy its nature. The x-ray evidence strongly suggests that it was not a tumor arising in the mucosa of the bowel. If it was a tumor of the cecal wall, it must have arisen from the outer layers of the bowel wall. Thus, it seems to me that certain things can reasonably be excluded. We have no evidence to justify a diagnosis of carcinoma of the cecum. His age does not exclude it, but he had had symptoms for a year, he probably had had little or no blood in the stools, since he had a normal red-cell count and hemoglobin, and there was no evidence of any ulceration of the mucosa by x-ray. I should be content to rule out a carcinoma of the cecum. Lymphoma, I presume, cannot so easily be excluded, because ulceration might not have been present. I do not know how to make that diagnosis with complete assurance, any more than I can exclude it. I am influenced by Dr. Lingley, who considers this to be pressure from without rather than an intrinsic process in the bowel itself. Someone might say that this was a mass of lymphomatous nodes giving pressure on the cecum, and that is a possible answer. If we talk about tumor arising in the bowel and not associated with or developing from the mucosa, we are limited to a lipoma. This could be present for a year without affecting the patient. It could cause recurrent episodes of pain and could be palpated perfectly well through the abdominal wall in a man who

was not very heavy. The recurrent attacks of pain would be due to attacks of intussusception, and these should be associated with periods of obstruction. But the bowels moved normally during attacks.

Among other conditions that are essentially of an inflammatory nature, tuberculosis can give a palpable tumor in this location. This is one of the commoner sites of the hyperplastic type of tuberculosis. I do not know much about it, but it seems to me that, if the patient had a process of that type involving the wall of the cecum, there would have been more clinical and x-ray evidence of bowel irritation. Also, the radiologist would not believe so definitely that it was something outside the bowel.

I think we need only mention various remote possibilities, such as diverticulitis of the cecum and regional enteritis.

I do not believe that the patient had true appendicitis, because I do not consider this primarily an acute inflammatory process. The location of the mass is entirely consistent with appendicitis. We do not know the interval between attacks. The last attack may have been three or four weeks before the present one. It is conceivable that the patient had one of the porky, large, chronically inflamed, low-grade inflammatory processes that occasionally involve the appendix and result in a mass in that region; such cases might very easily not present the usual findings that we associate with acute appendicitis. It is more likely that he had one of the large, dilated appendiceal tumors, such as a mucocoele, that are occasionally found at operation. It seems to me, then, that this is most easily explained by a process associated with the appendix. I do not believe that it was acute appendicitis. The other two conditions one would have to think of more seriously—and it does not make much difference how one puts them—are lymphoma, with a mass of nodes in this region, and lipoma.

A PHYSICIAN: How about a carcinoid?

DR. MCKITTRICK: That is included in the heterogeneous group of appendiceal masses.

DR. FRANCIS R. DIEUAIDE: Would a lymphomatous mass of nodes be likely to be so firm and associated with pain?

DR. MCKITTRICK: I do not know. I do not believe, however, that the symptoms were very severe. The patient went to New York, and the mass could be moved around in his abdomen. I am not paying too much attention to the tenderness.

DR. LANGDON PARSONS: As Dr. McKittrick pointed out, the history is a little unreliable, but

it is all that we could get. The patient was difficult to control.

We operated with a preoperative diagnosis of carcinoid, largely because there was a definite mass readily outlined that could be displaced toward the midline. This would not have been true of an appendiceal abscess.

DR. TRACY B. MALLORY: Do you want to describe the operative findings?

DR. PARSONS: There was a very large, dilated, nonadherent appendix, with a very firm base, which made me think that it had invaded the lower pole of the cecum and further suggested the possibility of carcinoid. The lower pole of the cecum was resected and turned in. The final diagnosis proved to be a mucocele of the appendix. An occluding web accounted for the hard and firm base.

#### CLINICAL DIAGNOSIS

Carcinoid of appendix.

#### DR. MCKITTRICK'S DIAGNOSIS

Tumor of appendix (? mucocele, ? carcinoid).

#### ANATOMICAL DIAGNOSIS

Mucocele of the appendix.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: The mass was just about twice the size of that described on physical examination—10 by 3 cm., instead of 5 by 2 cm. Its walls were very thin, and it contained clear, thin, mucous fluid. The base was completely occluded by an old scar process, as is always so in a mucocele. There was no carcinoid.

### CASE 28052

#### PRESENTATION OF CASE

A sixty-three-year-old man entered the hospital with the complaint of swelling in back of the left knee.

Two months before entry, he began to notice swelling of the posterior aspect of the upper leg just above the knee. The swelling rapidly increased in size, until at the time of entry it was as large as a grapefruit. Regularly during the night, the mass decreased to about half its volume in the daytime. The patient had no pain or other symptoms, and his general health was very good. He had lost about 10 pounds in weight during the year before entry. The past and family histories were otherwise irrelevant.

Physical examination revealed a well-developed,

well-nourished man in no acute distress. The heart, lungs, and abdomen were normal. Bilateral inguinal hernias were present, and there was moderate, symmetrical enlargement of the prostate. On the posterior aspect of the lower portion of the left thigh, there was a large, soft, smooth, slightly movable, nontender mass measuring 15 by 12 cm. It did not transilluminate, and no bruit could be heard over it. There was no limitation of motion or pain on motion of the joint.

The temperature was 98°F., the pulse 80, and the respirations 20. The blood pressure was 120 systolic, 70 diastolic.

Examination of the urine was negative. The blood showed a red-cell count of 4,860,000 with 90 per cent hemoglobin, and a white-cell count of 9450 with 73 per cent polymorphonuclears. The nonprotein nitrogen was 29 mg. per 100 cc., and the blood Hinton reaction was negative. An x-ray film of the left knee showed a round, well-defined, soft-tissue mass measuring 15 by 12 cm. behind the lower end of the femur. The mass was homogeneous, and denser than the surrounding tissue. It displaced the calcified femoral artery slightly to the right. There was no definite evidence of involvement of the bone.

An operation was performed on the fourth day.

#### DIFFERENTIAL DIAGNOSIS

DR. RICHARD H. WALLACE: Our problem is to determine the nature of a localized, rapidly growing mass of short duration, in a man who apparently was well and in whom the other findings were essentially normal.

There is nothing to suggest that the mass was inflammatory or granulomatous in origin, and from the description, the skin was not involved. The x-ray films rule out any involvement of bone, so that the origin of the swelling must have been in the intervening soft parts.

No bruit was heard, no pulsation was noted, and the calcified artery was displaced by the mass, so that we can rule out aneurysm.

One of the commonest swellings behind the knee joint is a synovial diverticulum, frequently called Baker's cyst, for the man who described it. These, however, present in the popliteal space and bulge downward into the upper portion of the lower leg. Tumors of the fibroma or neurofibroma group are too firm to fit the description in this case. Lipoma is not uncommon in this area, and I cannot rule it out; however, the growth was too rapid for one that had not become sarcomatous.

The change in size with rest in bed, with increase in the morning, suggests blood-vessel origin, or a very vascular tumor, but a superficial one of

this size should involve the skin and should not be homogeneous. The impression of a "bag of worms" is common in the hemangiomas, and both this tumor and the lymphangiomas usually decrease in size rapidly with elevation of the extremity.

Myosarcoma is found in this region and can be one of the most rapidly growing of all tumors. Its softness also fits the description, and the apparent change in size at night may have been due to its partial disappearance beneath the large muscles of the thigh when they were relaxed and the protrusion of the tumor when the patient was in the upright position, because of gravity and muscular contraction.

I believe the most likely diagnosis is myosarcoma or some mixed sarcoma with a myxomatous element.

#### CLINICAL DIAGNOSIS

Neurofibrosarcoma

DR WALLACE'S DIAGNOSIS

Myosarcoma

#### ANATOMICAL DIAGNOSIS

Liposarcoma of thigh

#### PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY. The exact diagnosis of a tumor of this character must almost always await the report of the pathologist's histologic examination. The clinician can merely speculate on the relative probabilities of the various tumors to be found in the given area. To tell the truth, it often makes little difference what the type of cell turns out to be, and the more essential decision is an estimate of the degree of malignancy. The benign tumors can be safely incised locally within their capsules, the low grade malignant tumors

are prone to recurrence if so handled and often deserve a block dissection, and the highly malignant tumors must be treated either with extensive block dissection or even with amputation.

Dr. Wallace guessed a myosarcoma, and the clinicians on the wards a neurofibrosarcoma. An incision was made over the tumor, and a rather soft, lobulated, apparently encapsulated mass was shelled out without much difficulty. In the laboratory, we made an unusual diagnosis—liposarcoma. The frequency with which this diagnosis is made varies considerably from one laboratory to another and also within the same laboratory from one five year period to another. It is not an easy tumor to recognize with certainty, since unless it is so well differentiated that fat cells of the mature or at least the fetal type are formed, one has nothing to rely on but the presence of spindle cells containing demonstrable fat. The presence of fat in a tumor cell is not particularly unusual, however, and may indicate not a metabolic activity but merely a degenerative phenomenon. Since the cells of highly malignant tumors frequently, one might almost say usually, show degenerative changes in certain areas, I must confess that I cannot interpret the presence of fat droplets in tumor cells and that I am rarely confident in making the diagnosis of liposarcoma. In this case, however, so many grades of transition from nearly adult fat cells, through multivacuolated cells of the fetal type to frank spindle cells were present that I believe the diagnosis could scarcely be doubted.

The patient made a rapid postoperative recovery, and was discharged without further treatment. A follow up note eighteen months later states that four months later a high amputation was done in another hospital, presumably for recurrence and that for the fourteen months following the second operation, he had had no further trouble.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston, Massachusetts.

## PROCUREMENT AND ASSIGNMENT SERVICE

ACCORDING to a recent statement issued by the Procurement and Assignment Service, which appeared in the January 17 issue of the *Journal of the American Medical Association*, some confusion has arisen regarding the enrollment forms that were printed in the December 27 and January 3 issues of the *Journal of the American Medical Association* and in the January 1 issue of the *New England Journal of Medicine*. The form was intended only for those men *immediately* available for military service; this was implied by the first paragraph, in spite of the fact that the last two questions on the blank were such that misinterpretation inevitably followed. As a matter of fact,

it is now acknowledged that the continued registration of physicians *under thirty-six years of age who are immediately available* will suffice to meet the current needs of the military services.

The statement goes on to say that "the physical requirements for service with every military, governmental, industrial and civil agency"—the last two appear to be difficult to define—will be published shortly, so that each physician himself can determine what type of service he is physically qualified to enter. Following this, a new questionnaire and enrollment form, as well as a list of the military, governmental, industrial and civil agencies that require medical services, will be mailed to all physicians. On this form, the physician is given the opportunity to state that he is willing to volunteer his services for the duration of the emergency and to express his preference for the type of agency. The Procurement and Assignment Service will then issue a certificate of enrollment and a numbered button as evidence that the enrollee has offered to assist in the interests of national defense and that his offer has been formally recognized and accepted by the Procurement and Assignment Service.

## MEDICAL EDUCATION AND THE WAR

THE entry of the United States into the war creates an impressive series of responsibilities for the medical schools of the country. It is necessary not only to maintain but actually to increase the production of physicians to meet the needs of the armed forces, the defense industry and the civil community. Fortunately, medical students have been permitted to continue with their studies, partly through the wise point of view of the heads of the Selective Service System and partly through the admission of third-year and fourth-year students to the Medical Administrative Corps Reserve—it is hoped that the latter provision will be extended to include all medical students and even those accepted for admission by an approved school.

The total enrollment of medical schools is now larger by about 300 students than it was a year ago; however, convinced that even this is not

enough to satisfy the demand, the Association of American Medical Colleges has recommended a program of accelerated medical education. On December 29, Boston University School of Medicine, Harvard Medical School and Tufts College Medical School announced their plans to begin the next academic year on July 1, and to operate thereafter on an essentially continuous program. Such a plan, if generally adopted, will increase the production of physicians by 33 per cent during the next three years. The program has difficulties and hazards, but is certainly the safest way to bring about the needed increase.

It is the duty and privilege of medical schools to supply their share of medical officers to the fighting forces. But it is highly important that teaching staffs and research staffs be maintained at an effective level, since the calls on these services are going up and not down. Continuous operation means more teaching, and the program of defense research is growing rapidly. It is a matter for great satisfaction that in the Procurement and Assignment Service recently established in Washington there is an effective final common path for problems of medical personnel. This agency not only will deal with procurement as such but also will be concerned with the maintenance of essential services in hospitals, medical schools and other organizations.

There is room for imagination and industry in the meeting of problems imposed by war on colleges, medical schools and hospitals, throughout the successive phases of medical education. Perhaps, from these experiments of necessity, things may be learned that will help make medical education shorter, less expensive and better.

## MEDICAL EPONYM

### MÉNIÈRE'S DISEASE

The first full account of this syndrome appeared in a "Mémoire sur des lésions de l'oreille interne donnant lieu à des symptômes de congestion cérébrale apoplectiforme [Note on Lesions of the Internal Ear Giving Rise to Symptoms of Apoplectiform Cerebral Congestion]," which was printed in the *Gazette médicale de Paris* (3rd series,

16: 597-601, 1861), less than a year before the death of its author, Prosper Ménière (1799-1862), *chef de clinique* of the Paris Medical Faculty. A previous publication, "Sur une forme de surdit  grave d pendant d'une l sion de l'oreille interne [On a Form of Severe Deafness dependent on a Lesion of the Internal Ear]," had appeared in the *Bulletin de l'Acad mie imp riale de M decine* (26: 241, 1860-1861). The following is a translation of a portion of the former article.

1 An auditory apparatus that has previously been perfectly healthy may suddenly become the seat of functional disturbances consisting of noises of a variable nature, continuous or intermittent, and these noises are soon accompanied by more or less diminution of hearing.

2 These functional disturbances, which have their seat in the internal ear, may be followed by such apparent cerebral symptoms as vertigo, faintness, unsteady gait, giddiness and falling, furthermore, they are accompanied by nausea, vomiting and syncope.

3 These symptoms, which are intermittent, are soon followed by progressively serious deafness, and frequently the hearing is lost suddenly and completely.

4 Everything leads one to believe that the essential lesion behind these functional disturbances lies in the semicircular canals.

## MASSACHUSETTS MEDICAL SOCIETY

### COMMITTEE ON MATERNAL WELFARE

#### CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1940 (*continued*)

##### MEDICAL DISEASES

Forty-two deaths were caused by medical diseases (Table 1).

*Cardiac disease.* Among the 15 cases caused by cardiac disease was 1 patient with congenital heart disease who at autopsy proved to have a patent ductus arteriosus. Six days after delivery, this patient died of progressive cardiac decompensation.

Six cases were associated with cesarean section. Two of these patients had toxemia, and the circulatory failure of which they died was probably due to cardiac asthma. One patient with rheumatic heart disease had been advised against pregnancy, and when pregnant had been advised to have an abortion; she was hospitalized during pregnancy, and died shortly after operation. One patient on whom a cesarean section was done became very much worse while under treatment in the hospital. Cesarean section was performed, and death occurred a few hours later. One patient with chronic endocarditis was seen by a cardiologist at the beginning of her pregnancy and,

with his advice, was told that it was safe for her to have a baby. This patient died, six weeks after delivery, very suddenly of acute heart failure. An elderly primipara, forty-four years old, was delivered by cesarean section because of a high

TABLE 1. *Deaths due to Medical Diseases.*

CAUSE	No OF DEATHS
Cardiac disease	15
Pneumonia	14
Chronic nephritis	3
Meningitis	2
Chronic bronchiectasis	1
Acute yellow atrophy of liver	1
Pemphigus	1
Idiopathic thrombocytopenic purpura	1
Pulmonary tuberculosis	1
Tuberculous peritonitis	1
Ulcerative colitis	1
Fracture of skull	1

breech presentation, and died forty-eight hours later of cardiac dilatation and pulmonary edema.

One cardiac patient who arrived at the hospital practically moribund died fourteen hours later, undelivered. The investigator says, "As a matter of fact, this patient should have received treatment for her cardiac condition long before she became pregnant." Another patient who died undelivered was never seen early in pregnancy, and when finally seen she was not in labor and was moribund; she died immediately afterward. Another patient, at six months, arrived in the hospital with congestive heart failure and died eighteen hours later, undelivered.

One patient with chronic heart disease went through her pregnancy and delivery without difficulty, but three weeks later, when at home, she rolled over in bed, and suddenly expired. Another patient, who was known to have chronic heart disease complicated by nephritis, had had seven previous pregnancies. Abortion had been advised. This patient went through a full-term delivery; she returned to the hospital four weeks after discharge and died of cardiac decompensation and coronary thrombosis two weeks later. Another patient, in whom a diagnosis of chronic endocarditis had been made and for whom abortion had been advised, was delivered after a short premature labor by forceps and, two weeks following delivery, died of progressive heart failure.

These fatal cases of cardiac disease during pregnancy accentuate the fact that pregnancy results in death in the presence of certain complications.

*Pneumonia.* Two cases of pneumonia were associated with cesarean section. One patient developed definite pneumonia on the fourth day post partum and died a week later. An autopsy was performed, and bilateral bronchopneumonia was found. She was treated with sulfanilamide. In

the other case, pneumonia developed immediately after operation, and the patient died on the third day post partum.

Three cases of pneumonia were characterized as influenzal in type. One patient died eight days after spontaneous abortion, another eight days after delivery, and another delivered prematurely at seven months and died twelve days later. The patient with influenza following abortion did not develop the disease until five days after the spontaneous abortion, and she was dead three days later.

In the other cases of pneumonia, 1 patient had a spontaneous delivery almost at term and died four hours later; she was ill for about three days. One patient with lobar pneumonia had a spontaneous abortion at about three months and died shortly after being admitted to the hospital. Another delivered spontaneously when about five and a half months pregnant and died four days later; she was treated with sulfapyridine. One patient with lobar pneumonia died undelivered at eight months. One patient was delivered by forceps, developed a temperature immediately after delivery, and died on the seventh day; she also was treated with sulfapyridine. One patient delivered normally developed pneumonia following nitrous oxide and ether anesthesia and died two and a half days later. It is probable that the anesthetic had something to do with this death. At post-mortem examination, consolidation of all lobes of the lungs was found. Another patient, following operative delivery, died of bronchial pneumonia within forty-eight hours. Another patient, who entered the hospital with a fever and signs of pneumonia, delivered herself normally but died of bronchopneumonia twenty-six days after delivery. In the other case in which pneumonia was the cause of death, an operative delivery was performed, and fever and rales appeared the day after delivery; death occurred four days later.

So far as pneumonia is concerned, the fact that so many of these patients went into premature labor and still succumbed shows how serious this complication is in pregnancy. Obstetricians must impress on their patients that all colds during pregnancy should be treated with respect, and that any cold accompanied by fever should immediately be reported to the physician, so that the patient may be hospitalized, if necessary. In this way only may an early diagnosis of pneumonia be established and may chemotherapy be started in time to be of benefit. The incidence of fatal bronchopneumonia following cesarean section once more emphasizes the hazard of postoperative pneumonia. It should always be taken into account before ce-

sarcin section is elected. Undoubtedly, some of these cases developed pneumonia because of unsatisfactory anesthesia. It is regrettable that so many patients go into labor soon after the ingestion of a heavy meal. Vomiting of undigested food during anesthesia will sometimes cause particles to lodge in the lungs, with either collapse of the lung or subsequent pneumonia. This possibility cannot be avoided.

**Chronic nephritis** The first of the patients in this group was known to have had nephritis following scarlet fever, and after consultations with three physicians, abdominal hysterectomy was performed at about three months. The patient did well for five days and then failed and died. Autopsy showed acute yellow atrophy of the liver, as well as chronic nephritis. Another patient was delivered at about six months and died three months later of chronic nephritis. In the third case, which was one of known chronic nephritis of years' standing, the patient died undelivered at eight months.

These three cases illustrate the extreme hazard of any pregnancy superimposed on long standing chronic nephritis.

**Meningitis** One case of meningitis was due to a pneumococcus. This patient was excellently treated, but died at about five months, undelivered. An autopsy was performed. The other patient with meningitis, who died approximately six weeks after delivery, suffered a lung abscess caused by inhalation of vomitus during anesthesia, but the immediate cause of death was a meningitis of undetermined etiology.

**Acute yellow atrophy of liver** One patient died of acute yellow atrophy of the liver at about six months. Following an attack of grippé, the patient began to vomit, developed a temperature of 103°F and became jaundiced five days before death. A macerated fetus was delivered normally ten days before death.

**Pemphigus** One patient died of pemphigus, which developed along with unusually severe nausea and vomiting. During the course of the disease, she started to miscarry and was curetted, in spite of which she died two days later. There is little to be said about this case except its unusual nature.

**Idiopathic thrombocytopenic purpura** The patient with idiopathic thrombocytopenic purpura had had a normal delivery four weeks before admission to the hospital. In spite of twenty-one transfusions and the administration of cobra venom death followed. Autopsy showed multiple hemorrhages throughout all parenchymatous organs.

**Pulmonary tuberculosis** The patient who died at seven months of pulmonary tuberculosis had been admitted to a sanatorium one day before labor started. Of course, this patient never should have become pregnant.

**Tuberculous peritonitis** There was one case of tuberculous peritonitis. Miscarriage preceded abdominal operation by six weeks. The patient died five weeks after the operation.

**Ulcerative colitis** The patient who died of ulcerative colitis had been delivered normally five weeks previously. An abdominal operation preceded death.

**Fracture of skull** This patient, when seven months pregnant, was in an automobile accident and died undelivered very shortly after her admission to the hospital. Although the cause of death is not a "medical disease," the case is arbitrarily placed in this group.

## WAR ACTIVITIES

### UNITED STATES ARMY

The following medical officers entered on active duty in the First Corps Area between January 11 and January 17, 1942:

Patterson, John C., Lieut., of Boston. Manchester Air Base, Manchester, New Hampshire.  
Grulee, Clifford G., Lieut., of Boston. Fort Devens, Massachusetts.  
Maech, John V. S., Lieut., of Shelburne, Vermont. Fort Devens, Massachusetts.  
Witte, Max E., Capt., of Bangor, Maine. Fort Devens, Massachusetts.

General Hospital No 5 was recently mobilized at an Eastern Seaboard camp. This hospital, organized by the Harvard Medical School, is a continuation of Base Hospital No 5, which actively functioned in France during World War I. The officer personnel is as follows:

**Acting Director** Lieutenant Colonel Thomas H. Lannan.

**Surgical Service** Lieutenant Colonel Thomas H. Lannan, chief; Major Augustus Thorndike, assistant chief; Majors Edwin F. Cave, J. E. Dunphy, Carlyle G. Flake, John H. Harrison and Robert Zollinger, Captains Thomas W. Botsford, Thomas Cavanaugh, Stanley O. Hoerr, Lee G. Kendall, John L. Newell, T. B. Quigley, Charles P. Sheldon, Fiorindo A. Simeone, Dean W. Tanner and Richard Warren, First Lieutenants Chilton Crane, Charles L. Dimmler, Jr., Robert G. Snow and Robert R. White.

**Medical Service** Lieutenant Colonel Theodore L. Badger, chief; Major Eugene C. Eppinger, assistant chief; Majors Harold F. Corson, J. E. Greene, Stanley Kimball, Harold Levine, Charles May and Henry N. Pratt, Captains Arthur Baldwin, Richard V. Ebert, Charles P. Emerson, Joseph Frothingham, Paul Kunzel, Jack D. Myers, Carey M. Peters, Gordon A. Saunders and Roy L. Swank, First Lieutenants Samuel Asper, Henry H. Brewster, Joseph H. Burchenal and Sibley W. Hoobler.

*Laboratory Service:* Major Dale Friend; Captain Joseph H. Bragdon; First Lieutenant Richard Ford.

*X-ray Service:* Major Magnus I. Smedal; Captain Donald P. Ham; First Lieutenant Ralph C. Moore.

*Headquarters:* Captain John J. Kneisel.

*Registrar:* Majors J. Beach Hazard and Norman Vaughan, Quartermaster Corps; First Lieutenant Frederick P. Ross.

*Mess:* Major George F. Wilkins.

*Dental Corps:* Major Moses S. Strock; Captains Henry J. Carney, Harry Stone and George Sullivan; First Lieutenants Maurice Dinnerman, Gerald L. O'Neill and Maxwell Perman.

## CIVILIAN DEFENSE

### UNITED STATES OFFICE OF CIVILIAN DEFENSE

President Roosevelt has appointed Dr. George Baehr, chief medical officer of the Office of Civilian Defense, to be a member of the Health and Medical Committee of the Office of Defense Health and Welfare Services. Dr. Irvin Abell, chairman of the Committee on Medical Preparedness of the American Medical Association, is chairman of the committee, and the other members are Surgeon General James C. Magee, Surgeon General Ross T. McIntire, Surgeon General Thomas Parran and Dr. Lewis H. Weed, chairman of the Division of Medical Sciences of the National Research Council. The Office of Defense Health and Welfare Services is a part of the Office for Emergency Management, which, in turn, is part of the Executive Office of the President.

The Medical Advisory Board of the Office of Civilian Defense held a joint meeting with the regional medical officers at the national headquarters in Washington on December 8 and 9.

Coming immediately after the outbreak of war with Japan, the conference took on special importance. Mayor LaGuardia, United States Director of Civilian Defense, addressed the group briefly, urging action on two counts: organization of emergency medical field units and designation of field casualty stations in the target areas on both coasts.

The medical defense officials decided that it is necessary that blood banks, as well as collecting stations for plasma and serum, similar to those developed by the American Red Cross for the Army and Navy, be established for civilian use. It was pointed out that a supply of whole blood and of plasma and serum for use among civilians is essential, since the armed forces will not be able to release any of their supply under conditions of actual warfare.

Medical defense plans were reported to be under way in states along both seaboards in accordance with plans developed by the Office of Civilian Defense. Dr. Wallace D. Hunt, medical officer for the Ninth Civilian Defense Region, with headquarters in San Francisco, reported that the important cities of the West Coast, especially those in California, had well-developed disaster services as a result of their experiences with earthquakes, and that these were being rapidly integrated into a comprehensive civilian-defense program.

Members of the Medical Advisory Board who attended the meeting were Dr. George Baehr, New York City, chairman of the Board and chief medical officer of the Office of Civilian Defense, Dr. Robin C. Buerki, Philadelphia, Dr. Elliott C. Cutler, Boston, Dr. Oliver B. Kiel,

Wichita Falls, Texas, Dr. Albert McCown, Washington, and Dr. Huntington Williams, Baltimore. The regional medical officers present, in addition to Dr. Hunt, were Dr. Allan M. Butler, Boston, First Region, Dr. H. Van Zile Hyde, New York City, Second Region, Dr. W. Ross Cameron, Baltimore, Third Region, Dr. Judson D. Dowling, Atlanta, Georgia, Fourth Region, Dr. William S. Keller, Columbus, Ohio, Fifth Region, and Dr. Witten B. Russ, San Antonio, Texas, Eighth Region. Others present included Miss Mary Beard, director of nursing service, American Red Cross, Dr. James A. Crabtree, executive secretary, Health and Medical Committee of the Office of Defense Health and Welfare Services, Surgeon General Thomas Parran, Dr. Erval R. Coffey, United States Public Health Service, and Dr. Martha Eliot, United States Children's Bureau.

The second day was devoted to conferences with the United States Public Health Service, the Office of Defense Health and Welfare Services and the American Red Cross, whose part in the civilian-defense program was explained.

## MISCELLANY

### RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR NOVEMBER, 1941

DISEASES	NOVEMBER 1941	NOVEMBER 1940	FIVE YEAR AVERAGE*
Anterior poliomyelitis	10	4	4
Chicken pox	1171	1270	990
Diphtheria	15	10	13
Dog bite	698	641	662
Dysentery, bacillary	46	12	39
German measles	59	34	35
Gonorrhea	332	340	453
Measles	457	985	627
Meningitis, meningococcal	14	8	5
Meningitis, other forms	7	—	—
Mumps	692	389	364
Paratyphoid infections	5	2	4
Pneumonia, lobar	193	354	233
Scarlet fever	735	481	423
Syphilis	389	407	471
Tuberculosis, pulmonary	223	143	213
Tuberculosis, other forms	28	16	21
Typhoid fever	2	6	7
Undulant fever	5	4	4
Whooping cough	710	888	703

\*Based on figures for preceding five years.

### GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Actinomycosis was reported from: Chicopee, 1; total, 1.

Anterior poliomyelitis was reported from: Beverly, 1; Brockton, 1; Easton, 1; Haverhill, 1; New Bedford, 1; Quincy, 2; Somerville, 2; Southboro, 1; total, 10.

Diphtheria was reported from: Fall River, 6; Hingham, 2; Lowell, 1; New Bedford, 1; Springfield, 3; Watertown, 1; Wrentham, 1; total, 15.

Dysentery, bacillary, was reported from: Arlington, 1; Ayer, 16; Boston, 1; Fall River, 1; Ipswich, 4; Lowell, 7; Worcester, 16; total, 46.

Encephalitis, infectious, was reported from: Danvers, 1; Sterling, 1; Westford, 1; total, 3.

Meningitis, meningococcal, was reported from: Boston, 3; Bourne, 1; Braintree, 2; Brockton, 1; Framingham, 1; Hubbardston, 1; Lynn, 2; Medford, 1; Spencer, 1; Weymouth, 1; total, 14.

Meningitis, other forms, was reported from: Boston, 1; Braintree, 1; Brockton, 1; Gloucester, 1; Northampton, 1; Salem, 1; Winthrop, 1; total, 7.

Paratyphoid infections were reported from: Lawrence, 1;

Malden, 1; Northampton, 1, Westwood, 1, Winchester, 1, total 5

Pellagra was reported from Grafton, 3, total, 3

Septic sore throat was reported from Boston, 4, Medford 3, Worcester, 1, total, 8

Tetanus was reported from Boston, 1, Cambridge, 1, August 1, total, 3

Trichinosis was reported from Haverhill, 1, Milford, 1, total, 2

Trichinosis was reported from Boston, 2, total, 2

Typhoid fever was reported from Arlington, 1, Gardner 1, total, 2

Undulant fever was reported from Adams, 1, Lowell, 1, North Brookfield, 1, Warren, 1, Wellesley, 1, total, 5

Anterior poliomyelitis continued to show an increase over the usual seasonal incidence of a nonepidemic year

Dog bite and mumps showed record high incidences, this having been the third consecutive month for dog bite and the fifth for mumps

Meningococcal meningitis showed the highest incidence for November since 1922

Bacillary dysentery, chicken pox, German measles, paratyphoid infections, pulmonary tuberculosis, scarlet fever, and whooping cough were reported above the five year averages

Diphtheria, lobar pneumonia and measles were reported below the five year averages

Typhoid fever was reported at a record low figure with the exception of that for 1939, which was equaled

Animal rabies showed record low incidence, the single reported case having occurred in Woburn

## SCHOOL LUNCHES

The Joint Committee on Health Problems in Education of the American Medical Association and of the National Education Association, recognizing the increasing importance of school lunches, adopted the following statement at its regular annual meeting, held at Atlantic City, February 25 and 26, 1941

The school lunch serves an extremely important purpose from the standpoint of nutrition and practical health education. This being the case, the Joint Committee on Health Problems in Education calls attention to certain protective sanitary measures, knowing that the carrying out of these measures will help avoid sickness resulting from contaminated food

The educational aspects of school lunches, as well as the requirements for an adequate diet, have been presented in a report by the committee (*Health Education*, 1941 edition), to which the reader is referred. The index of this report furnishes many references to the educational value of the school lunch

For the purpose of assisting further, the following additional recommendations concerning lunchroom personnel and equipment are made

(1) All persons employed in the lunchroom must be scrupulously clean in person and attire. They should be required to submit to health examinations or procedures that the health or school authorities may see fit to require

(2) The lunchroom and kitchen must be clean and as well equipped as it is possible to expect under the existing circumstances in the particular school, it should be borne in mind that many poorly equipped schools are in very special need of school lunches from the standpoint of nutrition and education

(3) There must be present and in constant use the following equipment: a stove of such capacity as will furnish abundant heat for cooking and for heating large amounts of water, a place to wash dishes where they may be scalded with water over 170°F and allowed to dry, a supply of dishes and utensils sufficient to permit good practice in the handling of food, a clean, tight cupboard for the storage of dishes and utensils used in cooking, a supply of kitchen linen or its paper substitute great enough to permit sanitary handling of the food, and an icebox or refrigerator, if at all possible

(4) Food low in price is permissible, but it must not be fermented, decomposed, frostbitten, unclear or of unsanitary quality

Milk should be pasteurized. If unpasteurized, it should be *boiled* on the premises. If powdered milk is used, it must be mixed with safe water within an hour or two of the time it is to be used

Home canned fruits are safe, but home canned meats and vegetables may be used *only* after they have been removed from the can and boiled from three to five minutes

Leftovers are never to be carried over to the next day. All food prepared must be eaten, sent home with the children or put in the garbage *the day it is prepared*

Dry-old products are not to be used if there is any ingredient which is capable of spoilage or fermentation. This precaution is particularly needed with products containing cream fillings, meringues, or non-acid dressings or sauces, such as mayonnaise, whipped cream and French dressing

(5) The housekeeping of the lunchroom and the kitchen must be above criticism. Particular attention should be given to the exclusion of flies, rats, mice, roaches and other vermin. Containers that are vermin-proof must be provided when it is impossible to eradicate these nuisances

(6) The personnel and equipment must be under the daily supervision of some responsible person trained for such work,—school physician or school nurse, principal or home economics teacher,—who will have authority to order the abatement of a condition that may be dangerous. This responsible person shall decide whether a lunchroom worker is or is not fit to work on any given day. He shall take into consideration the following points and such others as seem pertinent or necessary to ensure safety to the persons eating the school lunch

(a) Is the individual clean in person and clothing?

(b) Is there suspicion that the worker is suffering from some communicable disease? If so, he should be examined by a physician or health officer who, in turn, should inform the administrative head of the school regarding the possible transmission of the disease. He should not be permitted to return to work after sickness or absence of undetermined cause until seen by a physician

(c) Is there any infectious disease, such as scarlet fever, in the home of the worker?

(d) Is there any skin disease or discharging wound?

The close co-operation of lunchroom directors, principals and school physicians, or health officers, is required if school eating places are to be safe. These individuals working together can see that sanitary precautions are

taken and thus prevent the spread of disease through foods.

Single copies of this statement are distributed gratis by the committee through its secretary, Dr. W. W. Bauer, 535 North Dearborn Street, Chicago. Quantities will be furnished at actual cost, prices being quoted on request. Requests for free copies must be made on the official letter-heads of school systems or public-health agencies.

#### MASSACHUSETTS TUMOR DIAGNOSIS SERVICE

Dr. Paul J. Jakmauh, commissioner of public health, has announced that, in the proposed change in the work of the Collis P. Huntington Memorial Hospital, the Tumor Diagnosis Service of the Massachusetts Department of Public Health will not be interrupted and will continue to be rendered at the Huntington building. If any change of location for this service proves necessary, ample notification will be given to the physicians of the State. The Tumor Diagnosis Service has been used with continually increasing frequency by the physicians of the State; hence, it is gratifying that the change in the administration of the hospital will not interfere in any way with this service.

#### BOOK REVIEWS

*How to Prevent Goiter.* By Israel Bram, M.D. 8°, cloth, 182 pp., with 21 illustrations. New York: E. P. Dutton and Company, Incorporated, 1941. \$2.00.

This book represents the views of a very limited number of people concerning the treatment of goiter. The author has insisted for years that goiter, particularly of the exophthalmic type, can be successfully treated by so-called "conservative medical treatment." The work is dedicated to "the men and women of science who seek to clarify the mysteries of glandular function," an undertaking, one must admit, of no small magnitude. In the preface, it is stated that the author has been asked from many quarters to address the general public on how to prevent goiter, which is the stated purpose of the book. It presents to the lay public a very reasonable discussion of the various types of thyroid disease.

There are a number of statements in the book with which one who has had any considerable experience with thyroid disease would disagree. One statement under the question of the use of iodine is: "While iodine in the treatment of exophthalmic goiter usually yields temporary benefit, it may give rise to a secondary harmful reaction which may endanger life." In a large experience with goiter, the reviewer has never observed such a condition.

Likewise, the statement is made that the author has seen the employment of iodine for a long time "productive of such enormous swelling of the thyroid gland as to result in almost fatal choking from pressure." In an experience now dealing with literally thousands of these cases, the reviewer has never seen such a situation.

In Chapter 13, "Prevention of Exophthalmic Goiter," under the heading, "The Type of Humanity Involved," the following statements are made: "Prior to the development of the disease [exophthalmic goiter] to which we may be susceptible, we may appear quite normal in the every-day sense of the word. Yet on careful examination there are certain earmarks by which one may distinguish susceptibility to tuberculosis, to diabetes, and to other diseases, including exophthalmic goiter. A timely recognition of the type of constitution of the individual may enable us to increase resistance to the malady in question."

This is typical, in the reviewer's mind, of many of the vague statements made by the author in this book and in his writings for professional consumption. Under the heading, "How to Reduce Susceptibility," occur further examples of the indefinite, intangible factors that those who are supposedly susceptible to this disease should avoid.

Under the heading, "High Lights in Treatment," is the following: "A successful outcome depends on individualization. While one patient may improve through the use of cold baths, in another these may produce nervousness. While many patients get along very well on a non-flesh dietary, most require the occasional addition of lamb chops, fish or fowl in order to avoid monotony of diet." Repeatedly in this monograph, one finds instructions to do this in one case and that in another. Here also is contained the statement, "Treatment must be broad and comprehensive, and if begun early, at least 90 per cent of patients will be rewarded by permanent restoration to health and happiness."

One can only say as this book, with its numerous photographs of before and after, is reviewed that it represents views that are not universally held. One cannot miss the implied criticism of so many thousands of people who have submitted themselves to surgery, even with its low mortality rate, and are satisfied with the results if as the author states, it is possible to accomplish the same things without surgery. In answer to the natural question that arises concerning the substantiation of the statement contained in this book, a method that can accomplish all that is promised will, if it is worth while, win its way with the public in spite of opposition, disagreement and everything else. When methods of treatment, surgical and those in this book, have been before the public for so many years, and when so few people accept and support the latter and more agreeable measures, it must be said that the verdict has been rendered by an intelligent and critical public.

*Native African Medicine, with Special Reference to Its Practice in the Mano Tribe of Liberia.* By George W. Harley, M.D. 8°, cloth, 294 pp., with 2 illustrations. Cambridge, Massachusetts: Harvard University Press 1941. \$3.50.

Dr. Harley, a skilled anthropologist and a missionary physician, spent many years in West Africa. In addition to his work as a missionary, he has made a very careful study of certain tribes, their religious and medical rituals, their methods for treating disease, and other matters of similar interest. The facts, as well as the theories behind the practice of medicine by the native African Negro, are clearly set forth in this book—a monograph of great interest to anthropologists and students of the history of medicine. Dr. Harley has analyzed the various drugs and poisons used by the natives and estimated their effectiveness in the treatment of diseases. He found that in ninety-nine diseases and pathologic conditions, the treatment was at least partially rational in most; moreover, he classified 65 per cent of the remedies used as clearly rational. The diseases were principally those with visible lesions, whereas those treated with magic were either serious or chronic or those that appeared with startling suddenness. The author concludes that there is evidence pointing to a tremendous number of valuable remedies used in African medical practice. The importance of this book, from the medical point of view, lies in his evaluation of the remedies that he saw used, as well as in his suggestions of their effectiveness. The volume, which is a skillfully written monograph recommended by the History of Science Society, can be endorsed as an outstanding study of the subject.

## THE USE AND ABUSE OF THE ELECTROCARDIOGRAM IN MEDICAL PRACTICE\*

H. M. MARVIN, M.D.†

NEW HAVEN, CONNECTICUT

SINCE it is impossible to discuss briefly and adequately either the uses or the abuses of the electrocardiogram, my comments must be restricted to a few of the major aspects. Because the value of electrocardiography is more widely recognized than its limitations, I shall devote more attention to the latter. I shall try to consider matters that lie within the range of my personal knowledge and experience, or those that are accepted as established facts by acknowledged authorities in this field; any apparent dogmatism in my statements is due solely to limitations of time.

\* \* \*

I shall consider very briefly a few of the more important ways in which electrocardiography can be of value in diagnosis and treatment; this discussion is not concerned with its advantages in laboratory research. I think one might mention first that this procedure is acknowledged to be the one certain method for the absolute identification of irregularities of the cardiac rhythm. It is true that electrocardiograms are often unnecessary for this purpose, for after several years of experience it is possible to identify most arrhythmias by means of auscultation alone. But there are circumstances in which clinical recognition is difficult or impossible, even for those with long experience, and at such times the electrocardiogram usually reveals the diagnosis immediately and clearly. If the arrhythmia is a complicated one, such as auricular fibrillation with a rapid ventricular rate complicated by frequent ectopic beats and short paroxysms of tachycardia, its certain identification is usually impossible without the aid of the electrocardiogram. Examples of this could be multiplied indefinitely, but the fact is too well established to require further discussion. This use of the

electrocardiogram is possibly its most significant one in clinical medicine.

Furthermore, the electrocardiogram occasionally gives valuable indications that the heart has been involved in the course of systemic diseases. It is particularly useful in rheumatic fever, diphtheria and trichinosis; in any of these diseases, it may provide the first—and indeed the only—evidence that the infecting organism or the toxin has affected the heart. It is probably justifiable to say that every patient who has one of these conditions should have electrocardiograms taken at frequent intervals, at least during the acute phase of the disease.

Again, these graphic records are usually of great value in the recognition of acute myocardial infarction, which is due in most cases to coronary arterial thrombosis. They often make it possible to identify cases of old, and previously unrecognized, myocardial infarction, but these are usually less important because the necessity for immediate and careful treatment is less urgent. In most cases, the curves not only reveal that there is a fresh infarct in the wall of the heart, but also point fairly clearly to the exact area involved, although I question whether this is clinically so essential as it was considered several years ago. Blumgart and his colleagues<sup>1</sup> have shown that coronary thrombosis with or without myocardial infarction has already occurred in many patients whose histories indicate nothing more than mild or moderate anginal pain on effort. It is now known that the electrocardiograms of many patients who are just beginning to experience such pain display the characteristic and progressive changes of recent myocardial infarction, and thus provide clear indications for the proper treatment at the proper time.

Occasionally, the electrocardiogram reveals clear evidence of digitalis intoxication that was unsus-

\*Presented before the New England Postgraduate Assembly, Cambridge, Massachusetts, October 29, 1941.

†Associate clinical professor of medicine, Yale University School of Medicine, and attending physician, New Haven Hospital.

pected by careful and competent physicians. Although in some of these cases a critical review of the history indicates that overdosage should have been suspected, in others the dose has not been large and the usual symptoms of toxicity have been absent. The great significance of this diagnosis perhaps needs no emphasis, but it is well exemplified by a patient whom I saw recently: a sixty-five-year-old woman whose chief symptoms were physical weakness and profound depression, with occasional hallucinations and periods of disorientation. She had been in bed for several weeks, and the mental confusion was increasing; the possibility of admitting her to an institution for the treatment of mental disease was being seriously considered. She had taken digitalis for some weeks in doses of 0.1 gm. ( $1\frac{1}{2}$  gr.) daily. Physical examination was entirely negative except for a third sound at the apex of the heart. The correct diagnosis—digitalis intoxication—was not suspected until the electrocardiogram was obtained; this showed incomplete auriculoventricular heart block, with a marked delay in auriculoventricular conduction, and depression of the RST segments. The third heart sound was due to the fact that the audible auricular contraction fell relatively early in diastole, and the mental symptoms were caused entirely by digitalis, since they disappeared completely after the drug was discontinued and reappeared in the same form when digitalis was resumed. This effect of digitalis is not especially uncommon in older people and is occasionally produced by relatively small doses, which may not affect the electrocardiogram so clearly as in this case. In another case, an excellent cardiologist made an unhesitating diagnosis of auricular fibrillation on the basis of auscultation of the heart when the condition was actually paroxysmal ventricular tachycardia, with alternation of upward and downward ventricular deflections due to severe digitalis poisoning. Fortunately, an electrocardiogram was obtained before the patient had received the large dose of digitalis that was prescribed. This mistake, which might easily have been made by anyone, emphasizes the necessity of securing these curves before proceeding with treatment, whenever it is feasible to do so.

Of less significance than any of the foregoing, but nevertheless not to be ignored completely, is the help that may be derived from the electrocardiogram in the recognition of structural lesions. Among the lesions that are sometimes reflected in changes in the curves are acute pericarditis and acute pulmonary infarction. I do not wish to place great emphasis on the role of the electrocardiogram in either of these conditions, be-

cause the changes are by no means constant and the diagnosis is often so clear from the clinical evidence alone that an electrocardiogram is unnecessary. Furthermore, there is not complete agreement as yet on the electrocardiographic pattern that should be accepted as indicative of pulmonary infarction, since this lesion may change the curves in a variety of ways. In chronic constrictive pericarditis, the electrocardiogram may provide evidence regarded by some as confirmatory, but it is not specific and the diagnosis should rest largely on other signs. Considerable emphasis has been placed on the presence of axis deviation of the electrocardiogram to the right or the left in the diagnosis of structural lesions that impose added work on the right or left ventricle. The classic association is that of right-axis deviation with mitral stenosis and of left-axis deviation with aortic valve lesions or arterial hypertension. But these matters seem to me of relatively little consequence, since axis deviation may depend on many factors besides ventricular enlargement, and the diagnosis of valvular lesions should be made by auscultation without great difficulty and with considerable confidence.

There is time to mention only one other circumstance in which the electrocardiogram may prove to be of great value. Those who specialize in the field of cardiovascular disease often have occasion to see people who are disturbed and apprehensive because of their belief that they have heart disease, when as a matter of fact they do not. Sometimes, this fear is based on unimportant symptoms, such as slight superficial stabs of discomfort over the precordium or the consciousness of occasional premature beats; sometimes—and far too often—on injudicious comments by physicians or nurses. It is unnecessary to mention the more serious conditions known as neurocirculatory asthenia and cardiac neurosis. In the treatment of such patients, it is imperative to convince them that everything possible has been done to ascertain the condition of the heart. An electrocardiogram is an essential part of the examination of every such person, and it may be a comfort both to him and to the physician to know that it is a normal one. I do not for one moment forget the well-known fact that a normal electrocardiogram does not exclude heart disease and may actually be obtained from patients who have heart failure; also I do not forget that a normal electrocardiogram, when combined with a negative cardiac history and negative physical and fluoroscopic or x-ray examinations, is vital additional evidence that strengthens the physician's belief that the heart is free from serious disease. This may be of psychologic value only, but

it is psychologic treatment that such patients need. I have known many patients—among them, a considerable number of physicians—whose burden of fear and anxiety has been greatly lightened by the knowledge that the electrocardiogram was perfectly normal.

This very hasty and incomplete survey of the contributions that the electrocardiogram may make to clinical medicine might be summarized by the statement that it identifies with certainty all known irregularities of cardiac rhythm, it may provide the first sign that the heart has been invaded by disease, it often shows in unmistakable terms that myocardial infarction has occurred, it may reveal unsuspected digitalis intoxication or serious poisoning, it sometimes provides help in the recognition of structural lesions in the heart or lungs, and it is often of great psychologic value in the examination of those who believe they have heart disease but whose hearts are actually normal.

\* \* \*

Having mentioned briefly some of the possible contributions of the electrocardiographic method to medical practice, I must now concede that the present widespread employment of this method may actually be doing more harm than good, if one excludes its use in large hospitals. I make this statement quite soberly, and shall attempt briefly to indicate some of the reasons that I believe to be responsible for this anomalous and deplorable situation. My comments do not apply to most large hospitals, and not at all to those investigators, teachers and clinicians who have brought the knowledge of electrocardiography to its present high level and are utilizing it daily in their work.

It may simplify the discussion of this matter if one remembers that abnormalities in the electrocardiogram, broadly speaking, consist of those associated with the arrhythmias on the one hand, and those in the conduction intervals and the ventricular complexes on the other. In general, the serious errors of interpretation are confined to the latter and not to the diagnosis of arrhythmias, although even these are often unidentified or misnamed. It is the changes in the ventricular complex, including its terminal portion, that are mainly responsible for the gross misuse of a valuable diagnostic procedure. And the first statement I wish to make is that the average practitioner who undertakes to interpret electrocardiograms does not realize, or refuses to believe, that the changes in this part of the curve have no specific significance whatever, with the single exception of changes associated with myocardial infarction. To express it otherwise, the alterations in the conduction intervals or in

the QRS complex and T wave on which he places emphasis in his diagnosis of coronary sclerosis or myocardial damage are not indications of any specific lesion in the heart, and may indeed be due to many causes other than heart disease. If this one truth could be accepted and remembered, most of the troubles with the method would end.

In the second place, the electrocardiogram almost never gives any helpful information about the functional state of the heart muscle, although thousands of physicians request such a record in the firm belief that the one who interprets the electrocardiogram will be able to determine exactly how much or how little activity the patient may be permitted. Actually, a very brief experience proves its uselessness in this respect and indicates what might be termed its positive and negative failure to portray the functional condition of the heart. For it has long been established beyond all possibility of doubt that the electrocardiogram may be perfectly normal in many patients whose hearts are seriously diseased, as in anginal or congestive heart failure. One may say with some confidence that the occurrence of acute myocardial infarction is about as clear evidence of coronary atherosclerosis as one can usually obtain during life, yet it is known that the conspicuous changes in the curve that often result from this condition may disappear wholly within a few months and thus leave the electrocardiogram normal. There is general agreement that a considerable percentage of patients who suffer from severe and unmistakable angina have normal curves, yet their hearts are abnormal. To indicate the failure of the electrocardiogram in the opposite direction, I need only state that certain well-marked alterations, often interpreted as indications of myocardial disease, may be found in the curves of persons who present no other signs of heart disease and who live for many years with no impairment of cardiac function and with no further change in the graphic records. Therefore, if it is known that a normal electrocardiogram may be obtained from a patient with advanced heart disease, and a distinctly altered curve from a person who has no clinical signs of heart disease, how can one possibly ask that the electrocardiogram reveal the functional condition of the myocardium? It is manifestly impossible, yet it is being asked scores of times every day.

A third misconception responsible for many errors is the fairly common belief that the electrocardiogram is an accurate quantitative indicator of the amount of digitalis active in the heart at a given moment. It is very difficult indeed to persuade some experienced clinicians that the record

will not tell precisely whether the patient needs a little more digitalis, a great deal more digitalis, or whether he has received a little too much and is on the verge of intoxication. As a matter of proved fact, the electrocardiogram will do no such thing. The curves from one patient may display marked changes preceding or accompanying the clinical signs of therapeutic effects, those from a second may show no changes (or very slight ones) when the patient is known to be fully digitalized, and those from a third may show only trivial alterations when there are clear signs of digitalis intoxication, as manifested by headache, nausea and vomiting. There are probably occasional cases in which the electrocardiograms give help concerning the administration of digitalis; it is quite certain that there are many in which they give none, and some in which they may actually be misleading if one is so foolish as to rely on these curves alone for guidance. The recent careful study of Geiger and his associates<sup>2</sup> has shown that depression of the ST segments, long regarded as an invariable effect of the administration of digitalis in therapeutic doses, occurred in less than half their digitalized patients. They also found—and this is perhaps of even greater consequence—that the onset and progression of such changes were not constant and were not quantitatively related to the amount of the drug that had been administered. Their study, which confirms the experience of many careful observers, indicates the impossibility of using the electrocardiogram as an index of the *degree* of digitalization.

There is another way in which these curves are often misused: some physicians still attempt to secure information about the prognosis from the electrocardiogram, although it has been shown again and again that this is usually impossible. In acute diphtheritic myocarditis, rapidly progressive changes in the ventricular complexes may justify the fear that death is imminent, and in occasional cases of acute myocardial infarction, similar progressive alterations may arouse the suspicion that the area of injury in the heart is larger and more serious than the clinical signs indicated. But even in these acute conditions, the graphic records must be interpreted in the light of the clinical evidence, while in chronic heart disease it is the clinical picture and laboratory data as a whole that must be used as the basis for estimating the prognosis.

Finally, and this is really but an amplification of my first criticism, misinterpretation of the electrocardiogram is responsible for a very large number of unjustified diagnoses of heart disease. The diagnosis of coronary disease is being made today

almost as freely as that of vitamin deficiency, and with far less justification. But I doubt if many physicians other than those who specialize in this particular field realize the extent of this error or the tragic consequences that often follow. I am speaking with deliberate conservatism when I say that every week scores, if not hundreds, of normal healthy subjects are restricted in their activities and made to suffer needless apprehension because of diagnoses of heart disease based on *minor* changes in the electrocardiogram alone, in the absence of all supporting clinical evidence. This statement is amply warranted by my own experience, but I do not limit it to my practice or to the State of Connecticut. Like all others who specialize in this restricted field, I see many curves taken in various parts of the United States, brought to me for the most part by patients who have been condemned to a life of semi-invalidism solely because of changes in the electrocardiogram. In most cases, these changes consist of such unimportant alterations as minimal slurring of the R or S wave in one lead, low voltage of the ventricular deflections in one or two leads, and the presence of a large Q wave or inverted T wave in Lead 3. My friends and colleagues in other cities tell me that their experiences are exactly similar to mine. But perhaps the best indication that this misuse of the method is not confined to one part of the country is the fact that the American Heart Association has received letters from leaders in the cardiovascular field in the East, the South, the Midwest and the far West, asking if some board cannot be established for the sole purpose of certifying those physicians who are competent to interpret electrocardiograms. And why? Because they have been appalled at learning how many wholly untrained and incompetent physicians have purchased electrocardiographs and are using them daily in their offices, with serene confidence in their ability to distinguish between the important and the unimportant changes in the curves. In many cases, their erroneous diagnoses would be merely ridiculous if they did not so often lead to tragedy in the lives of their patients.

I believe one of the principal reasons why the electrocardiographic method is doing widespread harm today is that many physicians overemphasize its value and underestimate its limitations. They confidently expect it to accomplish much the same things that a surgeon expects of an exploratory laparotomy: that it will disclose the nature of the pathologic process, reveal its exact location and extent, and tell a great deal about the immediate treatment and prognosis.

They fail to realize that it is purely a laboratory procedure, comparable in many respects with a roentgenogram or a leukocyte count. As such, the electrocardiogram is to be interpreted merely as one finding among many, and in the light of all the clinical evidence and other laboratory tests. With the exception of the arrhythmias and some cases of acute myocardial infarction, it is reprehensible to attempt an interpretation of the elec-

trocardiogram without knowing the clinical findings and the clinical diagnosis

## RIGHT-UPPER-QUADRANT PAIN ON EFFORT: AN EARLY SYMPTOM OF FAILURE OF THE RIGHT VENTRICLE\*

NORMAN H BOYER, MD,<sup>†</sup> AND PAUL D WHITE, MD<sup>‡</sup>

BOSTON

**P**AINFUL congestion of the liver at rest, due to sudden stretching of its capsule, during right-sided heart failure is frequently encountered. This must be regarded, however, as a fairly advanced stage of failure, just as dyspnea at rest must be considered a distinctly advanced stage of left-sided heart failure. Even as the stage of constant pulmonary engorgement is frequently preceded by a period during which additional loads put on the left ventricle may result in temporary flooding of the lungs with blood, so, we believe, there is a period of weakness of the right ventricle when a greater burden will result in temporary congestion of the liver. This organ forms a capacious blood reservoir and serves as a pool for the general venous circulation in the early stage of right ventricular failure. Patients are not uncommonly seen in whom the liver is enlarged, but in whom there is little or no obvious venous distention or increase in venous pressure, both in the early stages of failure and during the course of recovery from advanced failure.

In the case that initiated our interest in this subject in 1938, the patient was a twenty-one-year-old student who had always been well—except for attacks of rheumatic fever at the ages of five, fourteen and fifteen years—until six weeks prior to admission, when he began to feel poorly and to tire easily. Two weeks later, he went to his home, at an elevation of 8000 feet, where he became miserable with palpitation, upper abdominal discomfort and anorexia. He was digitalized at that time, but without much benefit. The striking thing in the history on admission to the hospital was that the only specific complaint was a "tight feeling"

in the right upper quadrant that came on regularly while he was walking up one flight of stairs at average speed and disappeared with rest. Physical examination revealed mitral stenosis, slight aortic regurgitation and auricular fibrillation. The only sign of heart failure at this time was a tender liver edge palpable two fingerbreadths below the costal margin. During the next two months, the patient developed progressive signs of right-sided heart failure, with distended neck veins and edema, and died with intractable congestive failure and rheumatic fever.

Following this experience, 3 more patients were encountered in whom the initial symptom of heart failure was pain in the right upper quadrant coming on with exertion and disappearing with rest. One patient was a forty-nine-year-old Negro whose chief complaint was right-upper-quadrant pain on effort. In this patient, an arrhythmia with tachycardia had been present for some years, and electrocardiography showed this to be auricular flutter with an auricular rate of 280 and an auriculoventricular block varying from 2:1 to 4:1, so that the ventricular rate averaged about 100 at rest. The electrocardiogram also showed inverted T waves in Leads 1 and 4, with a tendency toward right axis deviation. The blood Hinton reaction was positive, but there were no heart murmurs, and x-ray examination showed no obvious abnormality of the aorta or significant cardiac enlargement. The pulmonary second sound was not accentuated. There was calcification at the roots of the upper and lower lobes of the right lung, with considerable emphysema and diaphragmatic adhesion on the right. Albuminuria was constant, and there was moderate anemia. The arterial blood pressure was 120 systolic, 80 diastolic. The venous pressure measured 200 mm at first, but under treatment by digitalis, with reduction of the ven-

\*Presented before the New England Heart Association, Massachusetts General Hospital, December 16, 1940.

<sup>‡</sup>Lecturer in medicine, Harvard Medical School; physician, Massachusetts General Hospital.

tricular rate to 70 by an increase in the grade of block, it dropped to 96 mm. The liver was slightly enlarged. The patient was discharged in a much improved condition, with a diagnosis of auricular flutter and systemic venous congestion.

The etiology of this patient's heart failure remains obscure. At first, it was attributed to the effect of prolonged tachycardia, and this, in part at least, is doubtless the correct answer. He has since been followed for several months during which his failure has become progressively more marked, despite control of the ventricular rate by means of digitalis. The absence of signs pointing to pulmonary hypertension makes the usual causes of cor pulmonale unlikely. Recent x-ray evidence of increase of the heart shadow to the right, in addition to the electrocardiographic abnormalities, makes it probable that the chambers of the right side of the heart are involved primarily, whether from preponderant fatigue due to the tachycardia or from some unknown abnormality. Whatever the cause of the circulatory failure, the liver congestion was clear — at first, paroxysmal and, later, persistent.

Measurements of the circulation time and venous pressure were made on this patient before and after exercise. The exercise consisted in walking over the standard two-step stairs described by Master<sup>1</sup> at the rate of one trip in four seconds for a period of two minutes. It will be appreciated that this is only a very moderate grade of exercise, amounting to the ascent of two flights of stairs in a rather leisurely manner. Paraldehyde was the test substance used for measuring the circulation time from antecubital vein to pulmonary capillaries, the normal values by this method ranging from 3 to 9.5 seconds.<sup>2</sup> The venous pressure was measured by the direct method of Moritz and von Tabora.<sup>3</sup> The response of the venous pressure to exercise in normal persons is somewhat variable, depending on several factors — principally on whether the pressure is measured in an exercised or unexercised limb. According to McCrea, Eyster and Meek,<sup>4</sup> the pressure in the hand veins rises during and following exercises involving the use of the leg muscles. The rise may be several times the control value and may persist for over five minutes after cessation of the exercise. The extent of the rise depends in part on the severity of exercise and in part on the training of the subject. We have confirmed the finding of a rise in venous pressure following exercise in two normal persons. The finding of a comparable increase in the venous pressure after exercise in the patient with right-upper-quadrant pain and in another patient with a moderate degree of right ventricular failure

was of considerable interest. The response of the venous pressure to exertion thus does not necessarily provide a crucial index of the competency of the right ventricle, although this unexpected finding deserves further study.

The behavior of the circulation time proved to be more helpful in separating patients with normal hearts from those with impaired myocardial function. Figure 1 shows the results of the

FIGURE 1. *Arm-to-Lung Circulation Time Before and Immediately Following Exercise.*

circulation-time tests in the patient with right-upper-quadrant pain cited above, in a patient with a moderate degree of right ventricular failure on the basis of long-standing mitral stenosis but with no history of abdominal pain, and in a normal subject. Since it has already been established that the circulation time regularly decreases in normal persons after exercise,<sup>5, 6</sup> the data on one normal control subject has been included to indicate that the method used is applicable to the data derived from other methods. It will be seen that in the normal subject the arm-to-lung time before exercise was a little less than 9 seconds, and that after exercise it had shortened to a little less than 6 seconds. The patient with clinically evident right-sided failure began with a definitely prolonged

arm-to-lung time,—that is, 12 seconds,— which was further prolonged to 16 seconds after exercise. The patient with the syndrome of right-upper-quadrant pain had a normal circulation time to begin with, but after exercise it rose to a definitely abnormal level. This abnormal reaction to exercise can be interpreted as meaning inability of the right ventricle to cope with the increase in venous return, with resultant slowing of the blood flow from the unexercised limb. Palpation of the patient's liver before and after exercise revealed no demonstrable change.

It has been our experience, as well as that of others, that the arm-to-lung time, although de-

dates for it by virtue of long-standing pulmonary hypertension secondary to mitral stenosis or, in a few cases, to left ventricular failure.

This direct questioning showed the reason why the symptom has not been emphasized heretofore and why it was mentioned in only 1 of 1000 case histories of congestive heart failure recently reviewed at this hospital. Only rarely was it of any severity, and it was frequently so overshadowed by subsequent developments as to lose significance in the patient's mind. The character of the pain was usually described as dull or aching in type, but also not infrequently as a feeling of tension or tenderness, and occasionally as quite

signed to measure the right-sided circulation, may be affected by congestive changes in the lung capillaries. Some patients with mitral stenosis therefore show prolongation of the paraldehyde time following exercise, even in the absence of significant heart failure. We were fortunate in encountering this patient with the signs of heart failure limited to the systemic circuit in whom changes of blood velocity, as measured by paraldehyde, could be evaluated in terms of efficiency of the right ventricle alone.

The following hint of the awareness of such a symptom as that under discussion was found in Vaquez's<sup>7</sup> book: "The functional disorders [of the liver] begin as subjective symptoms, slow digestion, belching of gas, bloating of the stomach, and a sensation of tension in the epigastrium and hypochondria which is aggravated by standing or walking." No other reference to this symptom on effort has come to our attention.

We have attempted to gather information on the incidence of this symptom and have found that in a small group of selected patients, numbering about 40, it was present in 18. The group selected for questioning were patients who either had definite right-sided failure at the time or were candi-

sharp. The commonest precipitating factor was walking, but the pain was induced in 1 patient by paroxysms of coughing, and in 2 patients, although the pain was paroxysmal, no precipitating cause could be elicited (Table 1). It disappeared, as exertional dyspnea does, after a few moments of rest.

The duration of the period of recurrence of this symptom seems to be short, usually a matter of two or three months, because, on the one hand, the patient regains some of his lost reserve or, on the other, failure progresses so as to stretch the liver capsule, when the probable mechanism of the symptom is lost. When 1 patient (Case 12) was questioned, he had only well-compensated mitral stenosis, but he was able to recall very clearly having gone through a period about four years previously when right-upper-quadrant pain on effort had been present. At that time, he was leading a very active life and doing moderately hard work. He consulted a physician and learned for the first time that he had rheumatic heart disease. He took his physician's advice to decrease his activity; the abdominal pain disappeared and had not recurred during the ensuing four years. Unfortunately, most of the other patients progressed to frank con-

gestive failure. Whether they might also have been spared advanced failure by the proper recognition and treatment of their early symptoms cannot be answered with confidence, but it seems likely that some, at least, might have been. Obviously, when a patient is precipitated into acute failure by, for example, auricular fibrillation with tachycardia, he may not pass through this stage of paroxysmal liver engorgement, but will at once present the more familiar picture of prolonged right-upper-quadrant pain and tenderness.

### SUMMARY AND CONCLUSIONS

We have recently encountered 4 patients in whom right-upper-quadrant pain, precipitated by exertion and relieved by rest, has been the presenting symptom of early right-sided heart failure. It is evidently due to acute congestion of the liver and is comparable to dyspnea on effort in early left-sided heart failure.

Direct questioning of a group of 40 patients

who already had clinically evident right-sided failure, or were likely candidates for it, revealed that the pain had been present at some time in about 45 per cent. It is a symptom to which the patient rarely attaches much significance, since it is usually of little severity and is overshadowed by more uncomfortable symptoms.

If the symptom is sought as diligently as the history of dyspnea on exercise, it may be found to be a fairly common and reliable warning of early weakness of the right ventricle.

## CONGENITAL HYDRONEPHROSIS IN THE LOWER HALF OF A DOUBLE KIDNEY\*

### Report of a Case

SIDNEY FEYDER, M.D.,† AND CLYDE L. DEMING, M.D.‡

NEW HAVEN, CONNECTICUT

**M**ASSIVE congenital hydronephrosis filling half the abdomen and associated with reduplication of the ureter and renal pelvis has heretofore not been recorded. It is recognized that reduplication of the ureter wholly or in part and slight or moderate hydronephrosis are frequently encountered at routine cystoscopic examinations. However, a hydronephrosis filling half the abdomen from the diaphragm down into the bony pelvis is a rare condition. Cystic tumors large enough to displace the intestines to the opposite side of the abdomen present intriguing diagnostic problems. The following case was completely and accurately diagnosed preoperatively.

### CASE REPORT

G. D. (B 8902), a 5-year-old boy, was admitted to the Pediatric Service of the New Haven Hospital for study because of an abdominal mass discovered by a physician during a routine physical examination. The patient was said to have always had a protuberant abdomen, which

had been growing steadily larger. There were no symptoms directly referable to the gastrointestinal or genitourinary tract, and the patient's general health had been excellent. Development and growth had been normal.

Examination revealed a well-developed and well-nourished boy who appeared to be in good health. The vital signs were normal, and the blood pressure was 100/58. Examination of the chest revealed no abnormalities. The abdomen was protuberant, with a marked rib flare, widening of the infrasternal angle and prominent, dilated superficial veins. The left side of the abdomen was larger than the right and was occupied by a smooth, cystic mass filling the left flank from the costal margin to the iliac crest and extending to well beyond the midline on the right. The remainder of the physical examination was negative.

Accessory clinical data were within normal limits. The blood showed a red-cell count of 3,870,000 with a hemoglobin of 12.5 gm., and a white-cell count of 8200 with a normal differential. The blood Kahn reaction was negative. Examination of the urine revealed a negative microscopic sediment and culture. The blood nonprotein nitrogen was 32 mg. per 100 cc. The tuberculin reaction was negative.

X-ray studies revealed elevation of the left leaf of the diaphragm and a large soft-tissue mass filling the left side of the abdomen. Gastrointestinal films showed the stomach to be displaced upward and to the right, with small and large intestinal loops pushed into the right half of the abdomen, the descending colon swinging in a curvilinear line over to the right (Fig. 1).

cated a massive hydronephrosis in the lower segment of a double kidney, with complete destruction of functioning renal tissue in that pole, associated moderate hydro-

FIGURE 6. *Surgical Specimen.*

lumbar incision, and the cystic mass approached posterolaterally (Figs 6 and 7). Two thousand cubic centimeters of straw colored fluid was aspirated, following which there was sufficient collapse to allow mobilization and removal of the kidney without difficulty. Because of a complex arterial blood supply, heminephrectomy was not done.

The collapsed cystic mass, consisting of an extremely dilated renal pelvis, measured 15 cm in diameter, and contained a small amount of kidney tissue, 4 cm in diameter, at the upper pole. Two ureters were found, one entering the cystic mass below and the other extending upward to enter a separate pelvis at the upper pole. The ureters were separate to a point about 5 cm above the bladder, where they joined. There was no evidence of ureteral dilatation. There was, however, moderate narrowing of the ureteropelvic junction to the lower pelvis. Microscopic study of representative sections showed approximately normal kidney tissue at the upper pole. Sections of the cyst showed thin strips of fibrous tissue in several layers, with intervening dilated calyces lined by a thin layer of epithelium.

Following operation, the patient made an uneventful convalescence and was discharged on the 20th postoperative day. A follow up 4 months later showed him to be in excellent health.

### DISCUSSION

Clinically, cases such as the one presented are significant because of the increased incidence of pathologic change associated with anomalies of the urinary tract. In Mertz's<sup>1</sup> series of 300 cases, 30 per cent were complicated by pathologic change, as compared with 37.5 per cent in Braasch and Scholl's<sup>2</sup> series. The latter authors found both segments most frequently affected by disease; how-

ever, in cases in which only one segment was involved, it was oftener the lower.

Among the pathologic lesions complicating reduplication of the ureter and renal pelvis, in the order of their frequency, are pyelitis and pyelonephritis, nephrolithiasis, ureterolithiasis, hydronephrosis and pyonephrosis due to ureteral obstruction, renal tuberculosis, essential hematuria, nephroptosis, neoplasm and ectopic ureteral implantation.

In reviewing a series of 101 cases of hydronephrosis in infancy and childhood, Kretschmer<sup>3</sup> found the highest incidence in the age group from five to seven years, 28 per cent occurring in this range. Of the various causes of hydronephrosis in this series, 24 per cent were associated with congenital anomalies of the kidney and ureter.

### SUMMARY

An unusual case of massive hydronephrosis in the lower pole of a double kidney, which was due to a congenital ureteropelvic-junction obstruction, with ureteral displacement, is presented. A correct preoperative diagnosis was made, and complete recovery was obtained following nephrectomy.

## PULMONARY TUBERCULOSIS AND PREGNANCY\*

ROBERT H. BAKER, M.D.,† AND ARTHUR D. WARD, M.D.‡

WORCESTER, MASSACHUSETTS

THE problem of pregnancy associated with tuberculosis has received a good deal of study, and considerable discussion has accumulated in the literature, yet there are few real scientific data of significance concerning it. All that we can hope to do in this paper is to add to the discussion and show how our results compare with those of other institutions.

This problem centers around the fact that pregnancy places an additional strain on a human system that is already devitalized and slowed down by tuberculosis. This added strain cannot but have an adverse effect on the prognosis. On the other hand, the enlargement of the uterus aids in immobilizing the diaphragm and putting the lungs at rest. Yet the marked physical exertion of the second stage of labor again has an adverse effect. In the puerperium, an already debilitated tuberculous patient must combat the effects of pregnancy and labor in addition to those of tuberculosis. It is relatively common to find a flare-up of a previously quiescent or undiagnosed tuberculosis during the puerperium. Accordingly, one must not only treat the tuberculosis itself but also prepare the patient for labor, which is a great strain and a marked physical effort even for a woman in good health; one must plan ahead with the type of collapse therapy best suited to each case, to assure adequate protection to the diseased lung during and following labor. If the patient has already been under treatment by some means of collapse therapy, the problem is somewhat simplified. It is then a question of maintaining the collapse to protect the lung. On the other hand, if the patient is already several months pregnant before the diagnosis is made, the problem of securing an adequate collapse is more difficult, especially when time is limited.

It can be readily seen, then, that each case must be studied individually, from the standpoint of both pregnancy and tuberculosis; this means that there must be co-operation between the obstetrician and the phthisiologist, who must plan together the steps to be taken in preparing the patient for labor. Interruption of the pregnancy by abortion is being advocated less and less,<sup>1-3</sup> because induced

abortion is at times as hazardous as a normal delivery. Abortion, when undertaken, should be performed before the fourth month of pregnancy. Some type of collapse therapy, if not already started, should, if possible, be used.<sup>4, 5</sup> The type of collapse therapy chosen concerns the lung lesion primarily, as well as the pregnancy. The collapse, which does not interfere with the pregnancy, aids in alleviating the symptoms of the tuberculosis—especially cough, which when severe may lead to abortion or premature labor. Seeley, Siddall and Balzer<sup>2</sup> report from the literature a total of 31 cases with thoracoplasty in which the patients went through 34 full-term pregnancies. Collapse therapy is most important during labor. The acute flare-up of the disease following labor is apparently due to the opening up of lesions as the result of a rapid descent of the diaphragm. Artificial pneumothorax can best prevent this effect; if pneumothorax cannot be employed, phrenic crushing will splint the diaphragm and keep it from descending. A case has been reported<sup>6</sup> in which descent of the diaphragm was prevented by artificial pneumoperitoneum induced by admitting 3000 cc. of air into the peritoneal cavity.

In labor, the first stage is entirely involuntary and requires no exertion on the part of the patient. Most of the second stage is voluntary, use of the abdominal muscles being required to expel the fetus. We believe that these patients should be spared the voluntary part of labor. For this reason, it has been the practice of the obstetricians connected with the Belmont Hospital to apply forceps as soon as there is full dilatation of the cervix. Various types of anesthesia have been used, but most of our patients have been delivered under nitrous oxide, oxygen and ether anesthesia. However, the method now employed with these patients is the one that has been found the most satisfactory: local infiltration with perineal block. This is considered safer than spinal anesthesia, and does not incur any of the hazards that may accompany inhalation anesthesia. Local anesthesia has been found to be very satisfactory by both the obstetricians and the patients.

Collins<sup>7</sup> reports that premature labor is no commoner in tuberculous than in nontuberculous patients unless there is an exhausting cough, hemorrhage, fever or marked debility. Other writers<sup>2, 8</sup> find abortion and premature labor slightly more

\*Presented at the annual meeting of the Trudeau Society of Boston, Worcester, May 15, 1941.

†Medical director and thoracic surgeon, Belmont Hospital.

‡Senior physician, Belmont Hospital.

frequent. In our series of cases, 9 out of the 11 infants were full term; the other 2 were one month premature.

A frequent complication,<sup>8</sup> especially in active tuberculous cases, is hemorrhage and shock due to slow involution of the uterus. When it occurs following delivery, it should be combated as promptly and effectively as possible; it can be

facilities of the Worcester City Hospital. The obstetrician who takes care of the patient is on the staff of both hospitals. When a patient goes into labor, she is transferred to the Worcester City Hospital; in uncomplicated cases, she returns to this hospital within twelve to twenty-four hours, and if she has been receiving pneumothorax, air is given on her return, and the collapse is maintained. The

FIGURE 1.

*The photograph on the left represents the x-ray film on entry of a patient who had advanced bilateral pulmonary tuberculosis, with infiltration throughout the entire lung and cavitation below the clavicle on the right and with moderate infiltration on the left, the photograph on the right shows the x-ray film after collapse of the right lung had been maintained for some time.*

guarded against by protection of the patient from long, tedious, exhausting labors and difficult traumatic or operative deliveries.

The babies born to these mothers should, of course, be isolated, particularly if the mother has a positive sputum. The mother should not nurse her child, and provision should be made for its care until it is certain that there is no possibility of communication of the disease.

Eleven cases of pregnancy associated with active pulmonary tuberculosis have been under the observation of the staff of the Belmont Hospital during the last seven years. We still have contact with each of the patients, all of whom are well at present; furthermore, the babies born to these women are living and well. Two patients have survived two pregnancies since they first underwent treatment for tuberculosis. In no case has there been a reactivation of the disease. At this hospital, the facilities for handling obstetric cases are limited. However, we have the use of the

baby remains at Worcester City Hospital until arrangements for its care can be made.

One case in this series was that of a para IV who was admitted to the hospital with the diagnosis of far advanced bilateral pulmonary tuberculosis and with a positive sputum; all the symptoms dated back to the recent pregnancy and confinement. Pneumothorax was given unsuccessfully on both sides. Later, a pneumolysis was performed, and a paraffin pack was applied on the right, followed by extrapleural pneumolysis and a paraffin pack on the left. Still later, a four-stage thoracoplasty and a phrenic crushing on the left were performed. Although this patient was not delivered during treatment for her disease, the case shows that pregnancy can aggravate the condition.

Another case was that of a gravida VI, para IV, who had received treatment for tuberculosis for four years before entry, and who was admitted with a diagnosis of moderately advanced unilateral tuberculosis. Pneumothorax was unsuccessful.

ful, and pneumolysis could not be done. A thoracoplasty succeeded in arresting the disease. The patient again became pregnant three years after the thoracoplasty, but aborted at two or three months; possibly, abortion was induced, although this never could be proved. Nevertheless, there was no flare-up of her disease.

A third case is that of a primipara believed to have moderately advanced unilateral tu-

again delivered by cesarean section. Convalescence was once more uneventful. Following each delivery, there was no flare-up of the disease.

One primipara and 4 multiparas had pneumothorax on one side. One of the multiparas has been delivered twice since treatment was instituted. Four of these 5 cases were classified as moderately advanced, and 3 had a positive sputum; the other was far advanced. Diagnosis was not

FIGURE 2.

*The photograph on the left shows the x-ray film on entry of a patient who had bilateral pulmonary tuberculosis, with infiltration of the upper half of the lung and cavitation below the clavicle on the left and infiltration of the apex on the right, the photograph on the right represents the x-ray film after bilateral collapse had been maintained for two years.*

berculosis at another hospital, where pneumothorax and pneumolysis were carried out. She was admitted when she was four months pregnant following a threatened miscarriage after she had failed for six months to report to the Outpatient Department for pneumothorax refills. At the time of admission, the lung was practically re-expanded. Obstetric consultants advised that the patient be allowed to continue her pregnancy. She was kept on general supportive treatment until the eighth month of pregnancy, when a phrenic crushing was done. When she came to term, there was considerable overriding of the fetal head because of a generally contracted pelvis, and it was elected to deliver her by cesarean section. Convalescence was uneventful. Eighteen months later, the patient was again admitted, when she was two months pregnant. Two months before term, the phrenic crushing was repeated. One week before term, signs of toxemia appeared, and the patient was

made in 1 case until the third month of pregnancy, and in 2 until the seventh month; pneumothorax was instituted in each case when the diagnosis was made. One patient had had pneumothorax for two years and had maintained a satisfactory collapse; another had had pneumothorax for four years, but at the time of pregnancy, the collapse was unsatisfactory, and two days before delivery a temporary phrenic crushing was done. The patient with far advanced disease was seven months pregnant at the time of admission; she was immediately given pneumothorax on the right, with a good result and relief of symptoms, particularly of a severe cough. All 5 of these patients went through an uneventful labor and puerperium, and 1 of them, who refused to be readmitted, has been delivered again, although not under our care.

Of 3 primiparas with a diagnosis of far advanced bilateral disease and with a positive spu

tum, 1 had been on bilateral pneumothorax for six years, and another for two years; a third, who was five months pregnant when the diagnosis was made, was started immediately on bilateral pneumothorax. All 3 would have had a guarded prognosis even without the added burden of pregnancy. However, in no case was termination of the pregnancy by abortion considered. The patient who had had bilateral pneumothorax for two years refused to come into the hospital when she became pregnant; her collapse was accordingly maintained in the Outpatient Department, and she was not admitted until she went into labor. The patient who had had bilateral collapse for six years was admitted one month before term and had a satisfactory collapse. Both these patients went through a normal delivery and uneventful puerperium. The patient who was five months pregnant at the time the diagnosis was made had a good collapse by the time she reached term and had an uneventful delivery. About one month following delivery, she began to have attacks of pain in the lower right chest and back. Subsequently, the attacks of pain radiated to the epigastric region, and on one occasion were associated with nausea, vomiting and chills. An intravenous pyelogram revealed a ptosis of the right kidney; the lower pole was rotated inward, giving faulty drainage. The ureter was also somewhat tortuous and irregular. The pain was relieved by symptomatic treatment, without recurrence. The patient later had a pneumolysis on the left when some of the adhesions were cut, but because of vascularity the larger adhesions could not be severed. A lysis could not be done on the right because all the adhesions contained large blood vessels. However, the sputum was negative, and the collapse has remained satisfactory.

Each of these patients was given the type of collapse therapy that was best suited to the particular lung lesion. Those who had had an unsatisfactory collapse from pneumothorax were further safeguarded shortly before delivery by a temporary phrenic crushing. The results in each case were satisfactory.

#### SUMMARY AND CONCLUSIONS

The necessity of adequate and proper treatment for the pregnant tuberculous patient is stressed.

If proper treatment is given, a therapeutic abortion because of pulmonary tuberculosis is rarely indicated. Risk of pregnancy in tuberculous women is no greater than that in the nontuberculous if the patients are properly treated. Those who become pregnant should be hospitalized and cared for by obstetricians and tuberculosis specialists.

Collapse therapy, preferably pneumothorax, should be instituted when possible and should never be discontinued during pregnancy. In active pulmonary tuberculosis, it is much more effective than therapeutic abortion.

After labor, treatment for tuberculosis should be carried on vigorously, and no successful collapse therapy should be discontinued without serious study.

## MEDICAL PROGRESS

### HETEROGENEOUS RENAL DISORDERS\*

JOHN H. TALBOTT, M.D.†

BOSTON

THIS discussion concerns disorders of renal impairment, functional and anatomic, that are not usually classified as renal disease. Since Bright's disease has been adequately covered in a recent progress report,<sup>1</sup> duplication of any significant portion of that article is avoided. Nor is any of the controversial material on the pathogenesis of arterial hypertension, which has been discussed by White and Smithwick<sup>2</sup> and Weiss,<sup>3</sup> presented. Thus, there is no discussion of the common varieties of acute or chronic nephritis, renal insufficiency in cardiac failure, hypertensive renal disease, congenital polycystic disease of the kidneys, toxemias of pregnancy with renal involvement, pyelonephritis, lipid nephrosis, amyloid kidney, renal stone or renal impairment from prostatic hypertrophy. A word of caution regarding renal impairment in cardiac failure is pertinent. With inadequate blood flow through the kidneys, renal function may be markedly depressed in the absence of marked anatomic changes. The severity of a renal disturbance should be judged only after relief of cardiac failure and restoration of renal blood flow.

#### DIABETES MELLITUS

Two types of renal disorder may develop in patients with diabetes mellitus. During acidosis and coma, the kidneys are subjected to grave insults. A disturbance of the acid-base balance of the blood accompanies ketosis, and is aggravated by the factors that lead to dehydration and shock—inadequate intake of water and salt, vomiting and polyuria. Impairment of ammonia formation ensues, and if the condition is untreated, the ability to excrete ketone bodies reaches a critical stage. Evidence of renal impairment is obvious from the clinical findings of oliguria and anuria and the laboratory findings of albuminuria, cylindruria and nitrogen retention in the blood. Microscopically, the kidneys of patients who have died from diabetic coma show cloudy swelling of the tubular

epithelium and relatively normal glomeruli.<sup>4</sup> The treatment of renal failure is an integral part of the treatment of diabetic acidosis. Restoration of the acid-base balance of the blood follows the judicious use of insulin, glucose, water and salt.<sup>5</sup> The possible development of acute renal failure is a strong argument in favor of constant vigilance toward restoration of water and salt content of the body; this may be neglected during rigorous treatment of the disturbance of carbohydrate metabolism.

The syndrome of diabetes mellitus, hypertension, albuminuria and intercapillary glomerulosclerosis has received considerable attention since its description by Kimmelstiel and Wilson<sup>6</sup> in 1936. Several features identify the syndrome clinically.<sup>7</sup> The incidence is considerably higher in female than in male patients with diabetes. The diabetes mellitus is usually mild, and may appear many years before the onset of hypertension and albuminuria. Sclerosis of the retinal vessels, hemorrhage, exudate and papilledema follow the development of severe hypertension. Albuminuria is usually massive and is presumably responsible for the designation "diabetic nephrosis." Persistent loss of albumin predisposes to edema formation. The albumin-globulin ratio is reversed, and doubly refractile lipid droplets are visible in the urinary sediment by examination with a polarizing microscope. Cardiac failure and nitrogen retention develop terminally. The characteristic pathologic lesion is an interlacing hyalinization of the central portions of the glomerular capillaries. The thickening arises in the intercapillary connective tissue, according to Kimmelstiel and Wilson,<sup>6</sup> whereas Allen,<sup>8</sup> who believes that it arises within the capillary walls, calls it a focal intramural glomerulosclerosis. The glomerular capsule shows deposits of hyaline and lipid material beneath the epithelium. Single glomeruli may be partially or completely hyalinized. The afferent arterioles show fatty and hyaline degeneration, and the efferent arterioles show arteriosclerosis. The lesion is easily distinguishable from the glomerulosclerosis of nephrosclerotic kidneys and from the glomerular hyalinization of glomerulonephritic kidneys observed in nondiabetic persons.<sup>7</sup>

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

## DIABETES INSIPIDUS

A dysfunction of the normal economy of the kidneys, rather than renal insufficiency, is a significant part of the pathogenesis of diabetes insipidus. With interruption or failure of consummation of the nervous impulses that normally traverse the supraoptichypophyseal tracts, the pituicytes of the neural hypophysis fail to elaborate a sufficient amount of antidiuretic hormone, and proper proportions of water and salt of the glomerular filtrate are not absorbed by the renal tubules. Polyuria, polydypsia and low urinary specific gravity (usually between 1.001 and 1.005) follow. The increased volume of urine excreted, contrary to casual impression, is not dependent on an increased rate of formation of glomerular filtrate. In fact, when glomerular filtration has been measured in patients with this malady, the value is on the low side of normal and not above normal.<sup>9</sup> The bulk of glomerular filtrate is reabsorbed by difference in osmotic pressure between blood and filtrate, and the antidiuretic hormone provides the stimulus for reabsorption of a smaller amount. The total reabsorption in a normal person is approximately 98 per cent. The excretion into the bladder of the remaining 2 per cent is sufficient to provide for a urine output of at least 2 liters. Reabsorption of glomerular filtrate in diabetes insipidus may be no more than 95 per cent complete. This reduction from the normal is sufficient to increase the daily urinary output to 10 liters. The percentile difference between reabsorption of fluid in a normal person and in a patient with diabetes insipidus, therefore, is not great.

## GOUT

The kidney has been held responsible for the pathogenesis and development of symptoms in patients with gout for several reasons. It is thought by some that a differential inability of the kidneys to excrete uric acid is the primary defect. I do not adhere to this assumption, for reasons presented elsewhere.<sup>10</sup> On the other hand, all students of the disease agree that renal insufficiency is a serious and frequent complication. This is thought to be caused by the burden imposed on the kidneys for the excretion of excessive quantities of uric acid. An increased excretion of uric acid might not be harmful to the kidneys if the solubility were similar to that of other salts, such as sodium chloride and potassium phosphate. The solubility of uric acid is not great, however, and the concentration in serum and glomerular filtrate in gouty patients is near the saturation point. When glomerular filtrate is concentrated in the

convoluted tubules of the kidney, the maximum solubility for uric acid is exceeded and urate salts are precipitated. Persistent precipitation of urate in the tubular lumens eventually leads to renal insufficiency.<sup>10</sup> Patients who develop gouty symptoms in the early decades of life may succumb to renal insufficiency before the age of fifty.<sup>11, 12</sup> Patients who develop symptoms later in life may live a normal span of years. In addition to precipitation of urates in the tubules, urate sludge may appear in the kidney pelvis and may serve as a nidus for urate calculi. The urate stones are friable, and surgical intervention usually is unnecessary should they become lodged temporarily in the ureter.

The subject of renal impairment in gouty patients has been one of great interest to our laboratory. Many of the findings have been published recently in a survey of 22 patients with gout.<sup>13</sup> In this study, the function of the kidneys was investigated by routine clinical procedures,—that is, by ability to concentrate solids, excretion of phenolsulfonphthalein dye, and intravenous pyelography,—as well as by the clearance technics.<sup>14</sup> The patients were selected without regard to extent of disease or duration of symptoms of gouty arthritis. Their ages varied from twenty-eight to eighty-one. With the various procedures used, 18 patients showed some limitation of renal activity. The ability to concentrate solids was observed most frequently. More than two thirds of the group had a depressed inulin and creatinine clearance. Four had severe renal impairment, as shown by an increased concentration of nonprotein nitrogen in the serum. Death ensued in each of these patients in from two to four years after the azotemia was detected. Pathological studies confirmed the clinical findings of renal damage. There was no characteristic renal lesion, however, except for the deposits of sodium urate in the tubules, which were visible grossly and microscopically. Diffuse vascular changes were readily apparent, regardless of age. Evidence of glomerulonephritis and pyelonephritis was also noted. Treatment of the morphologic renal disturbance in gout is supportive rather than specific. An abundant urine volume with an alkaline reaction is desirable. This allays precipitation of urates in the tubular lumens.

## ADRENAL INSUFFICIENCY

Patients with Addison's disease during an adrenal crisis suffer from impending or complete renal shutdown, in addition to the more commonly appreciated metabolic dysfunctions. The ability to excrete phenolsulfonphthalein dye is decreased

markedly, urinary solids cannot be concentrated, and the concentration of nonprotein nitrogen in the serum may be 100 mg. per 100 cc. or greater.<sup>15</sup> More precise tests of renal function, that is, urea and creatinine clearance,<sup>14</sup> may be reduced 50 per cent or more.<sup>16, 17</sup> The mechanism is chiefly from reduction of glomerular filtration and follows hypotension, dehydration, decreased blood volume and hyperproteinemia. During treatment of acute adrenal insufficiency, evidence of severe renal impairment vanishes as the glomeruli resume filtration. Complete restoration of renal function is not achieved, however, and patients with Addison's disease whose symptoms are controlled by treatment with salt and hormones continue to show evidence of renal deterioration. This includes inability to concentrate solids maximally, albuminuria and cylindruria, as well as a depression in clearance of Diodrast and inulin.<sup>18</sup>

Patients with adrenal insufficiency secondary to pituitary hypofunction show similar changes. The impaired inulin and Diodrast clearances may be attributed to vasomotor unresponsiveness, decreased metabolic rate, nonspecific effect of a chronic disease and a lack of specific action by one or more adrenocortical hormones.

#### HYPERPARATHYROIDISM

Parathyroid adenoma or primary hyperparathyroidism is usually complicated by renal disease. The development of the pathologic changes in the kidney is well understood. With an increased concentration of parathormone in the body, serum calcium is increased, and urinary excretion of calcium and phosphate is augmented. Precipitation of calcium phosphate in the urinary tubules and appearance of calcium phosphate casts in the urine follow. The precipitation of calcium salt is enhanced by an alkaline urine. Prolonged deposition of calcium phosphate, with tubular and interstitial damage,—complicated frequently by infection and hydronephrosis,—leads to gross calcinosis in the renal pyramids and renal calculi, and subsequently to clinical renal failure. Albright et al.<sup>19</sup> emphasize the importance of excluding hyperparathyroidism in any patient with renal calculi. Removal of a single parathyroid adenoma or, in a few cases, of two or more diffusely so-called "hyperplastic" glands prevents further deposition of calcium phosphate but does not restore irreparable kidney damage.

Parathyroid hyperplasia secondary to renal disease has been called renal rickets as well as renal dwarfism. The term "rickets" has been applied because the bone changes have been confused

with those seen in infantile rickets. The pathogenesis of renal rickets, however, is dissimilar to that of primary hyperparathyroidism or of infantile rickets. Diffuse hyperplasia of the parathyroid glands follows long-standing renal impairment.<sup>20</sup> The commonest cause of renal disease is a congenital anomaly of the genitourinary tract, although low-grade chronic nephritis, pyelonephritis, nephrosis and polycystic disease have been implicated in some cases. Even though renal damage begins early in life, the characteristic bone changes do not become evident until late childhood or adolescence. The blood pressure is usually normal throughout the disease.

Albuminuria, impaired concentrating ability, reduction of phenolsulfonphthalein excretion and nitrogen and phosphate retention define the amount of renal damage. At least three disturbances may be attributed to phosphate retention: increased output of phosphate in the gastrointestinal tract, impaired absorption of calcium from the gastrointestinal tract and hypocalcemia, and increased parathyroid activity and correction of hypocalcemia. These lead to abnormal bone formation and skeletal changes. At post-mortem examination, the kidneys are small, scarred and contracted—signs of a long-standing process. Histologically, they present diffuse sclerosis, obliteration of the glomeruli, and interstitial and intratubular calcification. Evidence of previous episodes of hypertensive nephrosclerosis is lacking. Attempts at restoration of renal function in renal rickets are fruitless. Considerable benefit to the bony structures can be achieved, however, by a high calcium intake and liberal amounts of a mixture of citric acid and sodium citrate.<sup>21</sup> Absorption of calcium is enhanced, and serum calcium is elevated, so that further stimulus to parathyroid activity is diminished. Normal deposition of calcium in bone is then possible.

Renal rickets with hypercalcemia is a rare syndrome, similar in many respects to typical renal rickets, but a different malady, nevertheless. A complete metabolic study of a patient with this syndrome has been reported from the Massachusetts General Hospital.<sup>22</sup> Renal tubular disease and inability to synthesize ammonia probably represent the underlying lesion. Increased amounts of calcium are excreted in the urine to replace ammonia, which is no longer formed. This leads to calcium depletion in the body, secondary hyperparathyroidism and decreased concentration of serum phosphate. It is therefore a low-phosphorus type of rickets as opposed to the usual high-phosphorus type.

## ALKALOSIS

Temporary impairment of renal function may follow an acute episode of alkalosis, and morphologic deterioration of the kidneys is a complication of prolonged alkalosis. Cyclic vomiting in children and incomplete pyloric obstruction in adults give rise to alkalosis from excessive loss of hydrochloric acid in the gastric secretions. The prolonged ingestion of alkalis produces a similar effect on the hydrogen ion content of body fluids. The inherent danger of renal damage during the Sippy treatment of peptic ulcer was pointed out nearly twenty years ago by Hardt and Rivers.<sup>23</sup> The majority of patients who take soda bicarbonate do not develop clinical symptoms of alkalosis, although some degree of alkalinity of the blood must occur in all.<sup>24</sup> Intolerance for alkalis, rather than excessive ingestion, may be responsible for the development of renal symptoms. Kidneys with a low reserve become inadequate under the load imposed by need for increased excretion of base. Many of the patients who develop renal insufficiency during alkali ingestion are in the age groups that have a high incidence of chronic degenerative disease. It seems advisable to have reliable information regarding renal function in patients with pyloric obstruction and vomiting, as well as in those under consideration for prolonged alkali ingestion, and to appreciate the significance of the development of calcium casts and urinary calculi. Pathological studies of the kidneys of 6 patients who had received large amounts of alkalis during life have been reported by Cooke.<sup>25</sup> The tubules were the site of gross degeneration, lipid changes and calcification, whereas the blood vessels, connective tissue and glomeruli showed little change.

Renal function has been studied by McCance and Widdowson<sup>26</sup> in alkalosis as well as after restoration of the acid-base balance of the blood. Clearances of inulin and creatinine were markedly depressed during alkalosis. Similar observations have been made in our laboratory. It is apparent that acute renal failure, which may develop as a critical episode in alkalosis from decrease in rate of formation of glomerular filtrate, is not necessarily associated with extensive anatomic damage.

## BILATERAL CORTICAL NECROSIS OF THE KIDNEYS

This is a rare condition: less than 100 cases have been reported in the literature. It usually develops in women during or immediately following pregnancy. The child is almost always stillborn. A few cases of cortical necrosis following severe infections, such as dysentery, cholera, diphtheria and pneumonia, have been reported in both sexes. A negative past history for renal disturbance is usu-

ally obtained. Oliguria or anuria may be the first symptom that suggests renal damage. Elevation of the blood pressure, nausea, vomiting, edema and convulsions follow. If any urine is passed, it contains albumin, casts and blood cells. Few recoveries have been reported<sup>27</sup>; in fact, the correctness of the clinical diagnosis may be in doubt if the patient recovers. The kidneys are enlarged at post-mortem examination. The capsules strip easily and reveal a smooth surface, with mottled areas of gray yellow and dark red. The pathologic changes are confined to the cortex; the medulla is normal. Microscopically, the interlobular arteries are occluded, and the area supplied by each artery shows various degrees of necrosis in the tubules, glomeruli and afferent glomerular arterioles.<sup>28</sup> Observers agree that the pathological finding common to most cases is a vascular disease, but agreement is lacking whether endarteritis begins in the glomerular tufts and spreads centrally or whether necrotizing lesions of the interlobular arteries give rise to thrombi with secondary ischemia.<sup>29</sup>

## DISSEMINATED LUPUS ERYTHEMATOSUS

Most patients with disseminated lupus show albuminuria, cylindruria and hematuria before death. These findings by themselves are not vital, since only a small percentage of patients with this malady suffer from renal insufficiency as the primary cause of death. It is significant, however, that once renal damage becomes evident, the prognosis is poor. Patients with this malady have been described who lived for several years without signs of renal damage, but died within a few months after this was evident.<sup>30</sup> A relatively frequent finding microscopically is the "wire-loop" appearance produced by hyaline thickening of the capillary walls.<sup>31</sup> There is also swelling of the glomerulus, cloudy swelling of the glomerular capsule, and irregularity and thickening of the basement membrane. According to Stickney and Keith<sup>30</sup>: "Clinically the duration of renal abnormality is much longer than the pathologic change would indicate: therefore, the disease either is not an ordinary glomerulonephritis or is of low virulence with slow progression. Possibly the changes are secondary to toxic processes and do not represent primary renal disease." The frequent occurrence of bacterial endocarditis, with renal emboli, is also responsible for anatomic changes.

## PERIARTERITIS NODOSA

The primary lesion in this malady is thought to be in the small arteries and arterioles. The vessels in the kidney are involved as part of the generalized disease. Renal findings usually noted

in periarteritis include albuminuria, cylindruria, hyposthenuria and red and white blood cells in the urinary sediment. The association of fever, polymyositis, polyneuritis, eosinophilia and renal disturbance justifies the consideration of this malady in differential diagnosis. Biopsy of a striated muscle is of great help in establishing a correct diagnosis.

### CONGENITAL HEART DISEASE

Patients with advanced symptoms of the tetralogy of Fallot<sup>32</sup> show albuminuria, poor concentration ability, azotemia and impaired pyelographic excretion of Diodrast. Structural changes in the kidneys may be attributed to one or more processes, which include venous congestion, anoxemia, acidosis, glomerular nephritis and subacute bacterial endocarditis with renal infarction. Routine clinical tests of renal function may be negative at earlier stages of the disease. A significant reduction in inulin and creatinine clearance,<sup>14</sup> however, may be demonstrated, as it was in several patients studied at the Massachusetts General Hospital in recent years.<sup>33</sup> This is an excellent example of the fallacy of concluding that the kidneys are normal if clinical tests only are employed.

In patients with coarctation of the aorta, all tests, including inulin clearance, may be negative except Diodrast clearance, which is depressed. The filtration fraction ( $C_r \div C_D$ )<sup>14</sup> may be increased to more than 25 per cent. Friedman and his associates<sup>34</sup> have assumed that reduction in afferent blood flow and renal ischemia is primary and is followed by elevation of blood pressure and efferent arteriolar spasm. Such an interpretation may prove eventually to be inadequate.

### NEPHROTOXIC AGENTS

#### *Hemoglobinuria, Transfusion Reactions and Black-water Fever*

The development of partial or complete suppression of urine following a transfusion is attributed to the agglutination of the donor's cells by the recipient's serum, with subsequent hemolysis and hemoglobinuria. The kidney lesion is primary in the tubules and is similar to that observed in black-water fever.<sup>35</sup> It is caused by precipitation of acid hematin from the glomerular filtrate.<sup>36</sup> As the hydrogen ion concentration of the glomerular filtrate changes from alkaline to acid in the distal convoluted tubules, hematin is precipitated and rapidly plugs the tubular lumens. Pathological examination shows varying degrees of degeneration of the tubular epithelium, and leukocytes, debris and hemoglobin in the lumens. There may be cellular infiltration and edema of the interstitial spaces.

The glomeruli are essentially normal. Opinion is divided concerning whether the pathologic changes result solely from mechanical plugging of the tubules or whether a toxic process is superimposed. Necrosis of the tubular cells and central focal necrosis of the liver argue in favor of a multiple pathogenesis.<sup>37</sup>

There is no specific treatment of anuria following hemoglobinuria. Appreciation of the factors that lead to a transfusion reaction may prevent it in some patients. Discovery of the Rh factor in blood grouping is a vital contribution in prophylaxis. This has recently been discussed by Hooker.<sup>38</sup> The early recognition of a transfusion reaction and cessation of further infusion of whole blood may be lifesaving. An intravenous infusion of an alkaline solution before the tubules have become plugged with acid hematin is theoretically sound, but it is of little benefit after the initial insult. From 100 to 200 cc. of sodium racemic lactate solution given intravenously will keep the tubular urine alkaline for several hours and prevent further precipitation of the degradation products of hemoglobin. Similar alkalization or ingestion of soda bicarbonate by mouth may be useful in the prevention of transfusion anuria in patients who receive several transfusions of apparently compatible blood. Symptomatic treatment of anuria should not be neglected. Maintenance of the normal concentration of the constituents of the blood from day to day should be attempted. Recovery has been reported after anuria of from ten to twelve days' duration and an elevation of the nonprotein nitrogen to 200 mg. per 100 cc. Since the glomeruli suffer only secondarily, renal function may be restored once the tubules become patent. The acid-base balance of the blood should be maintained as effectively as possible until such restoration occurs. Decapsulation of the kidney is discussed below.

#### *Crush Injuries*

A new syndrome, an effect of the total-war principle of World War II, has been described in the British literature by Bywaters and others.<sup>39, 40</sup> It occurs among air-raid casualties who have been buried for several hours under great pressure on one or more extremities. The victim appears to be in fair clinical condition on rescue, and the involved structures show little more than edema and local anesthesia. Thereafter, a series of events rapidly develops that includes impairment of nutrition of the affected limb, signs of progressive renal insufficiency, oliguria, cylindruria, albuminuria and azotemia, circulatory collapse and intractable vomiting. The blood urea may rise to levels of 300 mg. per 100 cc., and the serum

potassium to levels of 7 milliequiv. per liter. Amputation of the affected limb does not stay the lethal processes, and the victim succumbs within a few days or a week. Advanced degenerative changes and brown pigmented casts are seen in the convoluted tubules of the kidney at pathological examination. In place of hemoglobin from the red blood cells, the toxic agent is myohemoglobin,<sup>41</sup> liberated presumably from crushed muscles. This diffuses into the blood stream and is subsequently precipitated in the renal tubules. Janeway<sup>42</sup> has pointed out the desirability of early administration of alkaline fluids as a preventive measure. The problem deserves further study because of its importance in the treatment of civilian and military casualties. Furthermore, it is possible that a syndrome similar to this is an unrecognized industrial hazard following crush injuries in peacetime jobs.

### *Sulfonamide Derivatives*

There is considerable variation among the several sulfonamides regarding the untoward effects on the kidney. Renal complications following the use of sulfanilamide are rare. Sulfathiazole and sulfapyridine are frequent offenders because of the tendency to form crystals in the lumens of the renal tubules. The sulfonamides are handled by the kidney as urea is handled, that is, they are present in the glomerular filtrate in the same concentration in which they exist in the plasma, and are reabsorbed in part by the tubules; the portion not reabsorbed is concentrated and excreted. Precipitation of crystals at the point of concentration in the tubules is unavoidable if adequate fluid is not available for solution. Sulfathiazole crystals appear in the urine more frequently than sulfapyridine crystals,<sup>43</sup> probably because the excretion of the former is more rapid and larger doses are needed for satisfactory blood levels. Plugging of the tubules with crystals may have dire consequences. Hematuria, anuria and retention of nitrogen products are direct effects. Equally alarming is the retention of the acetylated form of the sulfonamides. Since the acetylated forms are much more toxic than the free forms, the situation deteriorates rapidly, and a vicious circle is established. Caution seems indicated, therefore, in the use of sulfonamides in patients with recognized renal impairment. Because sulfonamide calculi are nonopaque to x-rays, this method of examination is not helpful in detecting them. Frequent examination of the blood for the concentration of the free and acetylated forms and examination of the urine for red cells and crystals must be relied on.

Microscopic examination of kidneys damaged by sulfapyridine shows extensive deposits of the acetylated form.<sup>44</sup> There is marked dilatation of the convoluted and collecting tubules and glomerular spaces by precipitated material. The tubules in the cortex appear more uniformly affected than those in the medulla. The prophylaxis and treatment of renal complications following sulfonamide therapy are important. A change of drug must be considered if the concentration of the acetylated form rises in the blood. An increased fluid exchange is helpful in redissolving precipitated material. Alkalinization of urine enhances the solubility of acetylsulfapyridine. The detection of hematuria and crystalluria is a caution signal but is not necessarily a signal for cessation of the sulfonamides.

### *Mercury Bichloride Poisoning*

In acute mercury poisoning, the kidneys bear the principal insult, and many of the serious consequences can be traced to renal impairment. The tubules suffer most, and may be rendered functionless by the accumulation of large quantities of debris.<sup>45</sup> Complete cessation of renal function may persist for a week or longer, with an elevation of nonprotein nitrogen to levels over 200 mg per 100 cc, and as in transfusion anuria, recovery eventually follows. Specific treatment of bichloride poisoning—that is, the administration of sodium formaldehyde sulfoxalate—may be a lifesaving measure in some patients, but the problem of controlling the chief cause of death remains unsolved. Sulfoxalate must be given orally or intravenously within a few minutes after the initial absorption of mercury to be effective. The end product of the reduction of mercuric chloride by sulfoxalate in vitro is about half as toxic as mercuric chloride.<sup>46</sup> The effectiveness of sulfoxalate is enhanced in an alkaline medium, and the use of alkalis is therefore desirable. Other measures that should be instituted at once to prevent additional absorption or reabsorption include lavage of the stomach and rectum and washing of the mouth.<sup>47</sup> Supportive treatment after the initial damage has been done is equally helpful. Unending efforts should be expended toward the treatment of shock and the maintenance of the acid base balance of the blood, before, during and after anuria.<sup>48</sup> This includes the intravenous administration of whole blood, physiologic saline solution and alkaline solutions.<sup>49</sup>

### *Hepatorenal Syndrome*

This designation is introduced with reluctance, since reliable observers have expressed doubt regarding the existence of a syndrome of essential

kidney and liver deterioration. The association of kidney disturbance with jaundice and liver disease is sufficiently common, however, to warrant a discussion, in the absence of general acceptance of a clinical syndrome. The association may be as subtle as the appearance of casts, blood cells and albumin in the urine of patients with surgical jaundice, or it may be as pronounced as in severe eclampsia with advanced renal failure and extensive and irreparable liver damage. An excellent bibliography of the literature prior to 1939 is given in a paper by Wilensky.<sup>50</sup>

There appears to be some confusion in the minds of physicians concerning the statement in textbooks that the liver is the site of formation of urea and that in liver disease a decreased content of urea in the blood may therefore be noted. Bollman, Mann and Magath<sup>51</sup> observed that the conversion of amino acids into urea occurs exclusively in the liver in the dog, and that urea production ceases following total extirpation of this organ. Protein metabolism does not cease, however, and amino acids accumulate in the blood if they are converted into urea. In the clinic, a counterpart of this situation is unique.<sup>52</sup> If only a small amount of functioning liver tissue remains, this is usually sufficient to make some urea, and complete obliteration of functioning liver tissue, with inability to form any urea, is a terminal event of short duration. An increase in concentration of urea in the blood, or no change, is therefore usual in liver disease. In a series of 180 cases of jaundice from medical and surgical causes,—including hepatitis, cirrhosis, and benign and malignant obstruction of the biliary passages,—Meyer, Popper and Steigmann<sup>53</sup> found a moderate increase of nonprotein nitrogen in the blood (40 to 70 mg. per 100 cc.) in nearly 40 per cent, and values greater than 70 mg. in 10 per cent. The mortality rate increased with a rise in the nonprotein-nitrogen level. Furthermore, a change in concentration was of prognostic significance, and an increase of nonprotein nitrogen in conditions amenable to surgery pointed toward the urgent need for surgical intervention.

The pathogenesis of renal insufficiency in liver disease is not yet established. If the hepatorenal syndrome is a clinical fact, kidney deterioration may be an integral process. On the other hand, azotemia may be extrarenal in origin, because of increased breakdown of tissue protein, dehydration and so forth. Whichever may be the correct explanation, azotemia suggests glomerular as well as tubular disturbance. Similar conclusions have been deduced from the study of urea and creatinine clearances<sup>14</sup> in patients with jaundice. These may be reduced from 20 to 75 per cent below nor-

mal.<sup>53, 54</sup> The pathologic picture suggests a degenerative, rather than an inflammatory, process that varies in degree from simple cloudy swelling to extensive necrosis of the tubular epithelium.<sup>55</sup> Glomeruli show proportionately less involvement.<sup>56</sup> Similar pathologic changes have been noted in animals following injection of bile salts (sodium dehydrocholate).<sup>57</sup> A major contribution has been made by Ayer<sup>58</sup> in the study of autopsy material from 18 infants who died of congenital atresia of the bile ducts. A constant microscopic finding in all cases was that of casts containing iron-free, brown pigment. They were present principally in the distal convoluted tubules and the collecting tubules of the cortex. Glomerular lesions were found in only 7 cases; 4 of these showed isolated and partly hyalinized bloodless loops, without epithelial proliferation. The severity of the renal changes was not related to the changes observed in the liver. A similarity between the renal lesions in transfusion reaction, bichloride poisoning and obstructive jaundice was stressed.

### *Decapsulation*

The subject of decapsulation is of interest in a general discussion of nephrotoxic agents, since this form of therapy has been recommended in the treatment of anuria.<sup>59</sup> It is my opinion that nothing is to be gained by decapsulating anuric kidneys. If resumption of urine flow follows decapsulation, restoration would probably have followed conservative treatment. Since decapsulation is an extensive operation and patients with anuria are acutely ill, additional insults may be fatal and are best avoided. Recently, we had an unusual opportunity to study the effects of unilateral decapsulation in a young woman who developed anuria following a transfusion reaction. On the fourth day of anuria, the right kidney was decapsulated, and catheters were placed in both ureters. Resumption of urine flow began about twenty-four hours after operation. There was no difference, however, between the urine volume from the decapsulated kidney and that from the untouched organ. Six weeks later, after normal urine volume had been established for some time and the concentration of nonprotein nitrogen in the blood was almost normal, inulin and Diodrast clearances<sup>14</sup> were done. The ureters were catheterized again so that each kidney could be studied separately. A marked reduction in the rate of formation of glomerular filtrate and in renal blood flow was observed. More significant was the comparison of the two kidneys. No striking difference between the kidneys was noted in any of the functions measured. A

mathematical average of all functions, however, showed a slightly better performance by the untouched kidney in comparison with the decapsulated one. Our results are interpreted as implying that unilateral decapsulation in this patient had no beneficial action on renal function.

#### EFFECT OF POSTURE

##### Orthostatic Hypertension

McCann and Romansky<sup>60</sup> reported clearance studies on 5 patients with hypertension associated with nephroptosis demonstrated by intravenous pyelography. The blood pressures in all patients were elevated when they were erect. Following a period of bed rest of from two to five days, the blood pressures were normal in all except 1 patient. The rate of formation of glomerular filtrate was unaltered by a change in position. On the other hand, the renal blood flow in the erect position was reduced by as much as 50 per cent, with a concomitant increase in filtration fraction. The treatment of only 3 patients is discussed. Two had a nephropexy performed, and 1 was given a ptosis belt. The therapeutic results were not particularly impressive.

##### Orthostatic Albuminuria

The current teaching that orthostatic albuminuria is a thoroughly benign mechanism is probably correct, although strict diagnostic criteria should be applied before acceptance of the diagnosis.<sup>61 62</sup> Two important articles on this subject were written many years ago. Jehle<sup>63</sup> and Sonne<sup>64</sup> observed that orthostatic changes in renal activity occur usually in young, supple persons with a lordosis of the first and the second lumbar vertebra. This was evident from the following observations: when the patient was recumbent in bed, there was neither lordosis nor albuminuria; when the patient was recumbent in bed, with a pillow under the back, albuminuria appeared; standing produced lordosis and albuminuria; standing with the left foot on a stool corrected the lordosis, and the urine became clear. Sonne catheterized the ureters of 6 persons, and in no case was urine from the right ureter abnormal when the patient was erect; however, in 4 cases, the kidney on the left side became anuric, and in the remaining 2, the urine became albuminous. It was thought that the renal vein on the left was probably compressed by the vertebral column, since the vein crosses to the right of the midline. These clinical observations have been confirmed by Chapman<sup>65</sup> and Ryland.<sup>62</sup>

Ryland studied intravenous pyelography by Diodrast, creatinine clearance and urinary constitu-

ents in 5 cases. The excretion of Diodrast and glomerular filtrate was significantly depressed in the erect position in 2, and similar to that in the supine position in 3. All showed casts, red blood cells and tubular epithelial cells in the erect position.

##### March Hemoglobinuria

An excellent review of this subject by Gilligan and Blumgart<sup>66</sup> has appeared recently. This is thought to be a rare condition, but the authors anticipate an increased incidence among men engaged in military activities if the possibilities of its development are appreciated. Hemoglobinuria and hemoglobinemia appear in young healthy men after strenuous marches or runs. In some subjects, lordosis appears to be a factor. The hemoglobinuria is functional in that renal damage cannot be demonstrated. The precise pathogenesis of the disturbance has not been determined, although the similarity of orthostatic albuminuria is apparent. The prognosis is excellent.

#### GASTROINTESTINAL HEMORRHAGE

An increase of nonprotein nitrogen in the blood is a frequent accompaniment of massive bleeding into the intestine.<sup>67</sup> Several processes are responsible. Considerable quantities of hemoglobin remain in the stomach and intestines after severe hemorrhage, which, if assimilated, necessitates the excretion of excessive amounts of urea. The excess urea is cared for promptly, and azotemia is not observed if adequate fluids are available for excretion and if the kidneys are efficient. Usually, this is not realized because of interfering factors, such as shock, hypochloremia, dehydration and starvation, all of which are frequent sequelae of hemorrhage. Furthermore, patients suffering from internal bleeding are apt to be in middle or late life, ages that are accompanied by an increasingly high incidence of degenerative changes of the kidneys. Under conditions of stress, renal insufficiency is not unexpected.<sup>68</sup> Data contrary to this view have recently been presented by Stevens et al,<sup>69</sup> who have concluded that azotemia following blood absorption is unrelated to renal impairment. It is apparent that further investigation is indicated before either conclusion is accepted as final.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 28061

#### PRESENTATION OF CASE

A seventy-two-year-old housewife was admitted to the hospital because of pain in the right lower quadrant of the abdomen.

The patient was quite well until the morning of the third day before entry, when she became aware of pain in the middle of her back in the lumbar region. Following lunch, at which she ate less than usual, there was flatulence, but no nausea, vomiting or pain. Some relief was experienced after the patient took "soda" and peppermint in water and lay down. Moderate amounts of gas were passed by mouth and by rectum. The patient slept comfortably that night. The next day, the pain in the back and the abdominal discomfort were replaced by pain in the right lower quadrant of the abdomen. At times, this pain was sharp and stabbing, although without radiation, and at other times it was a mere soreness. Moving about in bed was especially painful; walking was less so. The pain was aggravated by cough and by deep respirations. Bowel movements continued normal, and there were no urinary symptoms, nausea or vomiting. On the day before entry, the pain continued unchanged.

The past history and family histories were not of significance.

On admission, the patient had questionably jaundiced scleras. The heart was within normal size, with sounds of good quality and an apical systolic blow. There were basal "atelectatic" rales in the back, but the lungs were otherwise clear. There was exquisite tenderness and spasticity in the right upper and lower quadrants of the abdomen, with rebound tenderness referred to a point opposite the umbilicus. This point appeared to be the site of maximum tenderness. Peristalsis was active, with sounds of normal pitch.

The temperature was 100°F, the pulse 95, and the respirations 25. The blood pressure was 170 systolic, 70 diastolic.

Examination of the blood showed a white cell count of 18,400 with 82 per cent polymorphonuclears. The urine was normal.

A roentgenogram of the abdomen showed considerable gas in the bowel, without dilatation. The kidney shadows appeared normal, and no stones were seen. The skeleton showed moderate osteoporosis.

An operation was performed immediately after admission.

#### DIFFERENTIAL DIAGNOSIS

DR ALFRED KRANES Before Dr. Hamlin starts his discussion, I may say that there was no question of jaundice in this patient.

DR. EDWARD HAMLIN, JR. May we see the x-ray films?

DR. JAMES R. LINGLEY Here are the loops of small bowel referred to in the record; they were not appreciably dilated. They appeared to be normal in size. Here is one loop, which is probably colon. I think that you can have that much gas in the small bowel just from abdominal pain.

DR. HAMLIN We have, then, an elderly woman with a pathologic process in the abdomen; this apparently progressed to a fairly well localized peritonitis in about twelve hours. The causes that might produce such a story and physical findings are, of course, numerous, and as always, one must first consider acute appendicitis. In an elderly woman, this would be a very good story, and the physical findings do not appear to be inconsistent with a diagnosis of acute appendicitis. The laboratory work all substantiates the diagnosis of peritonitis, or some acute episode in the abdomen, and I cannot exclude appendicitis. It is also possible, although much less probable, that she had acute cholecystitis. I was going to mention the questionable jaundice as possible substantiation of that diagnosis, but Dr. Kranes has ruled it out.

Numerous other processes should be mentioned as possibilities. Twisted ovarian cyst can produce a story and findings similar to these, with spasm masking the mass. Acute diverticulitis, possibly of the cecum, although rare, could produce such a story. However, one part of this history as printed *that seems to me of more significance than anything else* is the fact that the trouble began as pain in the middle of the back in the lumbar region. That should mean that the pain was initiated by a process, either retroperitoneal or in the mesentery, which would also be retroperitoneal. That brings up the possibility of pancreatitis, although this would be an atypical story indeed for pancreatitis, the localization of pain being particularly unusual. But it brings up the question, especially, in this age group, of mesenteric throm

bosis. Mesenteric thrombosis can give a story of this duration. It may be argued that the normal bowel movements and the amount of gas passed by rectum should disturb one, but there is usually no mechanical obstruction of the bowel in mesenteric thrombosis, and if the area to be traversed is not too long, it is quite possible for the bowel contents and gas to pass down through a loop of intestine devoid of peristalsis, much as they would through a hose pipe. It is not unusual to find normal movements in cases of mesenteric thrombosis. It would be interesting to know whether guaiac tests were done on the stools, because at some time or other the patient should have passed blood.

DR. TRACY B. MALLORY: None are recorded.

DR. HAMLIN: It is difficult to determine whether the thrombosis was primarily in the arteries or in the veins. The length of the story, perhaps, is significant in that respect, and I shall make a primary diagnosis of acute venous thrombosis of the small bowel.

DR. LELAND S. MCKITTRICK: Dr. Hamlin has not made it quite clear to me how he has arrived at this very good diagnosis. He may well be right. It is a good diagnosis, but I wonder what makes him think so definitely that this is mesenteric thrombosis instead of the commoner conditions appearing in that region.

DR. HAMLIN: I should say that, to my mind, the main point is the pain in the back, and I tried to bring that out as significant. The location of the point of maximum tenderness, close to the umbilicus, is also of some importance. All the laboratory work and the story seem to be consistent with such a diagnosis, and I am at a loss to think of anything else that would quite fill the bill.

DR. MCKITTRICK: Pain in the back is not an uncommon symptom in strangulation obstruction of the bowel. I have seen one case of infarction of a large ovarian cyst in which pain in the back was the presenting symptom, and I just want to bring that out. It is interesting that Dr. Hamlin has taken pain in the back as the point that has made him think of interference with the mesenteric blood supply.

A PHYSICIAN: The pelvic examination is not mentioned.

DR. CLAUDE E. WELCH: It was entirely negative.

DR. KRANES: I believed that the patient had an acute inflammatory process in the right side of the

abdomen, and that a possible interpretation of the back pain is an acute retrocecal appendicitis. I do not know how often that produces back pain, but a fair number of patients I have seen have had pain either in the flank or somewhat toward the back. Our preoperative diagnosis was acute appendicitis, with probable perforation and abscess formation, because of the exquisite tenderness and what felt like a mass on the right side. The mass was a little higher than one might expect with acute appendicitis. Dr. Welch saw her. He can tell what he thought about the situation.

DR. WELCH: The preoperative diagnosis was retrocecal appendiceal abscess,—although there were points that were not exactly consistent. For one thing, the operation was done at night, and something queer is always bound to turn up at that time. It was possible to palpate a mass under anesthesia. With a right-lower-quadrant (McBurney) incision, it was obvious that the appendix was not the cause. It was retrocecal and freed up easily. On further exploration, it was possible to feel a mass in the central portion of the abdomen. The incision was closed, and a paramedian incision revealed an infarcted twisted piece of omentum, about the size of a fist. In retrospect, this explains the pain in the back to which we had not paid adequate attention. It had a pedicle consisting of two blood vessels and nothing else. It had compressed the transverse colon but had not completely obstructed it. There may have been a good deal of pull on the mesentery of the bowel. The tip of the omentum had become anchored against the ascending colon a short distance above the cecum, and then proceeded on to infarction. The infarcted omentum was removed, and the postoperative course turned out to be uneventful.

#### CLINICAL DIAGNOSIS

Retrocecal appendiceal abscess.

#### DR. HAMLIN'S DIAGNOSIS

Mesenteric venous thrombosis.

#### ANATOMICAL DIAGNOSIS

Infarction of portion of the great omentum.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: The specimen which reached the laboratory was merely a segment of the great omentum, consisting of hemorrhagic, obviously necrotic, fat tissue.

## CASE 28062

## PRESENTATION OF CASE

A twenty-year-old, single female clerk was admitted to the hospital because of lower abdominal pain of twelve hours' duration.

On the evening before admission, immediately after dinner, the patient developed severe, cramping abdominal pain, radiating from a point immediately above the symphysis pubis to the epigastrium. This pain was fairly continuous, but there were acute, colicky exacerbations. She was nauseated, vomited five or six times, and felt most comfortable lying on her left side, with the thighs flexed.

The patient had been well prior to the acute onset of this illness. Six months before admission, she experienced a similar attack, which was relieved in a few hours by aspirin. The menses were regular, at intervals of thirty to thirty-two days. The last period occurred three and a half weeks before admission. The family history was irrelevant.

On admission, the patient appeared somewhat dehydrated. The tongue was coated. The heart and lungs were normal. There was tenderness in the lower abdomen in the midline and slightly toward the right, most pronounced about 5 cm above the symphysis. There was no spasm, but voluntary contracture was produced by pain. There was no rebound tenderness. The psos sign was negative. On rectal examination, there was marked tenderness in both vaults, more so on the right than on the left. The uterus seemed in normal position, with slight tenderness on movement of the cervix. The vaginal introitus was virginal.

The temperature was 97°F, the pulse 100, and the respirations 20. The blood pressure was 122 systolic, 70 diastolic.

Examination of the blood showed a white cell count of 14,000 with 95 per cent polymorphonuclears. The blood Hinton reaction was negative. The urine showed a + test for albumin.

On the first hospital day, an operation was performed.

## DIFFERENTIAL DIAGNOSIS

Dr S P SARRIS. The problem in this case is essentially the differential diagnosis of an acute condition of the abdomen. Of course, in most cases, practically speaking, the surgeon is primarily interested in distinguishing between the surgical and the nonsurgical abdomen. This decision is made generally, I believe, on the physical signs. When it comes to the individual differential

diagnosis of the various acute intra abdominal conditions, one comes up against a much more difficult problem, since the symptoms and signs are common to so many acute surgical emergencies that only through the variation of minute details and the sequence of the history can one make an accurate differential diagnosis.

On the basis of real peritoneal tenderness, as shown by abdominal examination and confirmed by rectal and pelvic examination, I am going to exclude all medical and nonsurgical conditions. The first diagnosis that I shall consider is, of course, the commonest of the acute intra abdominal surgical emergencies—acute appendicitis. It is true that one can almost never exclude acute appendicitis, however, I shall exclude that first and then continue. One of the reasons it cannot ordinarily be excluded is that appendicitis is so common that even its atypical forms are quite as common as any of the other rare intra abdominal emergencies.

The first specific point for comment is the history of abdominal pain of twelve hours' duration. I believe that the time is important. Most patients with acute appendicitis come in within the second, third or fourth twelve hour period. The fact that this patient came in the first twelve hours suggests that the pain was unusually severe. This point is confirmed later, when it is stated that the patient had severe, crampy abdominal pain. The pain in appendicitis is seldom very severe. It is more an "aggravating" type of pain. The onset, of course, is consistent with appendicitis, but I get the impression that this was a little more sudden than that in the average case of acute appendicitis. The character of the pain is consistent. The number of times that the patient vomited is rather against appendicitis. Usually, adults vomit either not at all or once or twice. This patient vomited five or six times within twelve hours. The previous episode of pain is consistent with appendicitis. Most patients give a history of a previous attack. When it comes to the physical signs I am influenced more by those not in favor of the diagnosis of appendicitis than anything else. The tenderness seems to have been more diffuse than it is with an acute appendix. With a history of twelve hours' duration, that much tenderness by abdominal, pelvic and rectal examinations is more consistent with a perforated appendix, but very few perforate in the first twelve hours. Furthermore, the temperature of 97°F is against the diagnosis of perforated appendix. Consequently, on the basis of the severity of the pain, the suddenness of onset, the frequency of vomiting and the

physical signs, I do not favor a diagnosis of appendicitis.

The next large group to consider is pelvic disorders. Fortunately, in this case, we have a vaginal introitus. The case would be much more difficult if the situation were otherwise, because I should have a hard time excluding salpingitis. As it is, except for the rare blood-borne form of salpingitis, we can quite well exclude that diagnosis. The same argument holds for all conditions that are related to pregnancy. We must consider a ruptured corpus hemorrhagicum; the pain came on suddenly, and the physical signs are consistent with that diagnosis. However, there are two important things against the diagnosis, the chief one being the colicky nature of the pain. In ruptured corpus hemorrhagicum, the onset is acute, but the pain is constant and is more of a soreness from peritoneal irritation than acute pain. Also, the last period occurred three and a half weeks before entry, and a ruptured follicle usually occurs midway between periods.

I think that I can exclude all conditions associated with the upper abdomen. The physical signs and the location of the pain all point to the lower abdomen. Then we have certain conditions, such as acute appendix epiploica and acute Meckel's diverticulum, that I think are practically impossible to diagnose preoperatively. One may suspect them because of certain atypical features, particularly in anyone who has had an appendix removed and has an attack similar to appendicitis. In addition, this patient is too young for diverticulitis.

I might say a word about ulcerative colitis. We have had two cases that began with acute severe, crampy abdominal pain and lower abdominal tenderness without diarrhea. One case we believed to be appendicitis, and the correct diagnosis was made only four or five days after we had ochsnerized the patient for probable ruptured appendix.

Finally, we come down to what we might suspect is the diagnosis in this case, and at this point I should like to ask if any flat abdominal films were taken in this case.

DR. TRACY B. MALLORY: No.

DR. SARRIS: Apparently, those who saw this patient did not consider small-bowel obstruction. If they did, I assume that they would have taken a flat abdominal film. We do not have the common finding in the past history of small-bowel obstruction,—that is, a previous operation,—but 20 to 30 per cent of patients with small-bowel obstruction have not had a previous operation. *There is no statement here concerning the bowels.*

Is there any about whether the patient's bowels had moved since the onset of pain, or about the passage of gas?

DR. MALLORY: I cannot find any.

DR. SARRIS: That would have helped, particularly if there had not been any bowel movement or passage of gas since the onset of the pain. I favor of the diagnosis of small-bowel obstruction are the sudden onset of the pain and its colicky nature. This patient apparently had continuous pain, with what is described as acute colicky exacerbations. There is no mention of the type of peristalsis this patient had—whether it was absent, present or increased. That is one of the most important physical signs of the diagnosis of acute small-bowel obstruction. So-called "obstructive peristalsis" is coincidental with acute exacerbations of crampy pain. The amount of vomiting is also more consistent with that diagnosis than with any other that I have mentioned.

DR. MALLORY: An additional note states that "peristalsis was present, but much diminished."

DR. SARRIS: Of course, I might have to change my diagnosis after that note. I should accept the finding if I were certain of the person who recorded it, because when one looks over the records of small-bowel obstruction, one of the features is the lack of consistency of that sign. One reason is, of course, that the examiner may not be looking for it. However, on second thought diminished peristalsis could be consistent with small-bowel obstruction if circulatory involvement of the obstructed loop had occurred. On still further thought, I shall not let that single finding talk me out of what I think this patient had. The amount of tenderness is consistent with something more than small-bowel obstruction—namely, circulatory interference in the obstructed loop. Tenderness in simple small-bowel obstruction is usually minimal, and if it is present, it is usually localized to the obstructing point.

We can probably exclude the commonest single cause of small-bowel obstruction in a patient not operated on, namely, intussusception, which occurs almost always in infants. The other causes are fairly equally distributed between congenital bands, volvulus, Meckel's diverticulum and foreign bodies, such as gallstones. I think that in this case we can probably exclude gallstones, and that leaves us with congenital bands and a Meckel's diverticulum. Finally, I wish to come back to the question of an acute Meckel's diverticulum, which as I said before falls in a group on which one cannot make an accurate diagnosis preoperatively. Furthermore, I have seen only one case of simple acute diverticulitis. Usually, this disease

is associated with massive gastrointestinal bleeding or small-bowel obstruction. Accordingly, unless this patient had small-bowel obstruction associated with a Meckel's diverticulum, I do not believe that I can make such a diagnosis.

My first diagnosis in this case is acute small-bowel obstruction, with probable, at least early, circulatory interference; my second diagnosis is acute appendicitis. Incidentally, I almost overlooked the possibility of a twisted ovarian cyst, which is, of course, fairly common at this age. However, I exclude it because of the character of the pain, and the fact that the examiners could not feel a mass. If they could feel the vaginal uterus, they should have been able to feel an ovarian cyst.

A PHYSICIAN: Is not the pain just over the symphysis low for small-bowel pain?

DR. SARRIS: I am glad you brought that up. Most textbooks state that the pain in small-bowel obstruction is at or above the umbilicus. In the series of cases that I looked up with Dr. McKittrick, we found one third or more with pain in the lower abdomen.

One other point regarding the diagnosis of acute appendicitis—we are not told that the pain had shifted. If a careful history is taken, one can elicit a shifting pain in acute appendicitis in as high as 85 or 90 per cent of the cases. I do not mean necessarily a shifting from the epigastrium to the right lower quadrant, but a difference in the character of the pain, vague and crampy, followed by tenderness—soreness more than pain. That is absent in this history, unless it was a case of acute appendicitis before localization. I remember one such case we thought had small-bowel obstruction, and while the patient was get-

ting x-rayed, over a period of two or three hours, the pain changed. When he came back to the Emergency Ward, he said that the pain had stopped, and he then could feel soreness on the right side. He had acute appendicitis. It is possible that this patient came in earlier than the average case and before localization.

#### CLINICAL DIAGNOSIS

Acute appendicitis.

#### DR. SARRIS'S DIAGNOSIS

Acute small-bowel obstruction, due to either a congenital band or a Meckel's diverticulum.

#### ANATOMICAL DIAGNOSES

Obstruction of small bowel.  
Congenital adhesive band.  
Gangrene of Meckel's diverticulum.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: The preoperative diagnosis on the wards was acute appendicitis. At operation, an infarcted piece of intestine, looking like small bowel on first examination was seen and on further exploration turned out to be the end of a Meckel's diverticulum. There was a congenital band, which contained a rather large artery, running across to the base of the Meckel's diverticulum. Behind it, three coils of small bowel had been caught so that there was intestinal obstruction. The Meckel's diverticulum was gangrenous but not perforated.

DR. SARRIS: How about the intestine itself?

DR. MALLORY: That was not infarcted. The appendix was removed and was normal.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston, Massachusetts.

## UNITED WAR FUND CAMPAIGN

THE quota of the Physicians' Group for the United War Fund Campaign is \$37,415. To raise this sum, seven hundred and fifty physicians must contribute \$50 each. Obviously, since many are unable to afford such a donation, others are expected to make up the difference.

At the close of the first week of the drive, January 29, approximately 25 per cent of the total quota had been received. This amount represents fair progress toward the realization of the goal, judged by the number of pledges made. However, many have given much more than \$50 per person—indeed, two physicians gave \$1000 each. And the sum pledged seems far less en-

couraging when compared with the donations received in the campaign as a whole: \$3,625,000, nearly 50 per cent of the \$7,600,000 goal.

Thus, it is apparent that only through generosity can the quota of the Physicians' Group be raised. Previous drives have shown that most substantial gifts have been received from those who have budgeted their pledges. Physicians are urged to give their fair share—in periodic payments, if necessary. They will thereby show their response to the patriotic and humanitarian appeal of this drive for victory on the home front and help for those who need it most.

## RECOMMENDATIONS TO MEDICAL STUDENTS AND PHYSICIANS CONCERNING THE NATIONAL EMERGENCY

THE following recommendations to medical students and physicians deserve detailed consideration by all concerned. The efficient utilization of the existing facilities offered by the medical profession and a guarantee of the continued functioning of all sources of medical education are so important in the present national emergency that the procedures advised in this statement by the Procurement and Assignment Service should not be unheeded.

### MEDICAL STUDENTS

All students holding letters of acceptance from the deans for admission to medical colleges as freshmen and sophomores of good academic standing in medical colleges should present letters have letters presented for them by their deans to their local boards of the Selective Service System. This step is necessary in order to be considered for deferment in Class II-A as a medical student. If local boards classify such students in Class I, they should immediately notify their deans and, if necessary, exercise their rights of appeal to the local boards of appeal. If, after exhausting such rights of appeal, further consideration is necessary, request for further appeal may be made to the state director and, if necessary, to the national director of the Selective Service System. These officers have the power to take appeals to the President.

Those junior and senior students who are duly qualified physically for commissions are to be recommended for deferment to local boards by their deans. These students should enroll with the Procurement and Assignment Service for other assignment.

All Junior and senior students in good standing in medical schools, who have not done so, should apply immediately for commission in the Army or the Navy. This commission is in the grade of Second Lieutenant, Medical Administrative Corps, Army of the United States, or Ensign H-V (P), United States Naval Reserve, the choice as to Army or Navy being entirely voluntary. Applications for commission in the Army should be made to the corps-area surgeon of the corps area in which the applicant resides, and applications for commission in the Navy should be made to the commandant of the naval district in which the applicant resides. A medical R O T C student should continue as before, with a view of obtaining a commission as First Lieutenant, Medical Corps, on graduation. Students who hold commissions, while the commissions are in force, come under the jurisdiction of the Army and Navy authorities and are not subject to induction under the Selective Service Act. The Army and Navy authorities will defer calling these officers to active duty until they have completed their medical education and at least twelve months of internship.

#### RECENT GRADUATES

On successful completion of the medical college course, every person holding a commission as Second Lieutenant, Medical Administrative Corps, Army of the United States, should make immediate application to the Adjutant General, United States Army, Washington, D C, for appointment as First Lieutenant, Medical Corps, Army of the United States. Every person holding a commission as Ensign H-V (P), United States Naval Reserve, should make immediate application to the commandant of his naval district for commission as Lieutenant (JG), Medical Corps, United States Naval Reserve. If appointment is desired as Lieutenant (JG), Medical Corps, United States Navy, application should be made to the Bureau of Medicine and Surgery, Navy Department, Washington, D C.

#### TWELVE-MONTH INTERNS

All interns should apply for a commission as First Lieutenant, Medical Corps, Army of the United States, or as Lieutenant (JG), United States Navy or Naval Reserve. On completion of twelve months of internship, except in rare cases in which the necessity of continuation as a member of the staff or as a resident can be defended by the institution, all who are physically fit may be required to enter military service. Those commissioned may then expect to enter military service in their professional capacity as medical officers, those who failed to apply for commission are liable for military service under the Selective Service Act.

#### HOSPITAL-STAFF MEMBERS

Interns with more than twelve months of internship, assistant residents, fellows, residents, junior staff members and staff members under the age of

forty-five, fall within the provisions of the Selective Service Act, which stipulate that all men between the ages of twenty and forty five are liable for military service. All such men holding Army commissions are subject to call at any time, and only temporary deferment is possible, on approval of the application made by the institution to the Adjutant General of the United States Army certifying that the individual is temporarily indispensable. All such men holding Naval Reserve commissions are subject to call at any time at the discretion of the Secretary of the Navy. Temporary deferments may be granted only on approval of applications made to the Surgeon General of the Navy.

All men in this category who do not hold commissions should enroll with the Procurement and Assignment Service. The Procurement and Assignment Service under the executive order of the President is charged with the proper distribution of medical personnel for military, governmental, industrial and civil agencies of the entire country. All those so enrolled whose services have not been established as essential in their present capacities will be certified as available to the Army, Navy or governmental, industrial or civil agencies requiring their services for the duration of the war.

#### PHYSICIANS UNDER FORTY FIVE

All male physicians in this category are liable for military service, and those who do not hold commissions are subject to induction under the Selective Service Act. In order that their service may be utilized in a professional capacity as medical officers, they should be made available for service when needed. Wherever possible, their present positions in civil life should be filled, or provisions made for filling their positions, by physicians over forty five, by physicians under forty-five who are physically disqualified for military service, by women physicians and by instructors and those engaged in research who do not possess an M D degree whose utilization would make available a physician for military service.

Every physician in this age group will be asked to enroll at an early date with the Procurement and Assignment Service. He will be certified for a position commensurate with his professional training and experience as requisitions are placed with the Procurement and Assignment Service by military, governmental, industrial and civil agencies requiring the assistance of those who must be relocated for the duration of the national emergency.

#### PHYSICIANS OVER FORTY-FIVE

All physicians over forty five will be asked to enroll with the Procurement and Assignment Service at an early date. Those who are essential in their present capacities will be retained and those who are available for assignment to military, governmental, industrial and civil agencies may be asked by the Procurement and Assignment Service to serve those agencies.

The maximal age for original appointment in the Army of the United States is fifty-five. The maximal age for original appointment in the Naval Reserve is fifty.

All inquiries concerning the Procurement and Assignment Service should be sent to the Executive Officer, 5654 Social Security Building, 4th Street and Independence Avenue, S.W., Washington, D. C., and not to individual members of the Directing Board or of committees thereof.

### "SPEEDING PRODUCTION OF PHYSICIANS"

UNDER this title, the January 17 issue of the *Journal of the American Medical Association* carries an editorial in which doubt is cast on the wisdom of the shortened schedule adopted by the medical schools of Boston and commented on in the January 29 issue of the *New England Journal of Medicine*. Briefly, the plan provides that the three months heretofore passed in the long summer vacation be eliminated, thus allowing the entrance and the graduation of a class every nine, instead of every twelve, months. After quoting "one leading educator" to the effect that the scheme had not received mature consideration, the editorial goes on to list five difficulties that have arisen. These problems and somewhat different interpretations of them are as follows:

(1) *As an emergency measure, the immediate gain is slight.* The gain may not be great, but it is real and predictable.

(2) *With the elimination of summer vacations, some students will be forced to discontinue their medical education, owing to their inability to earn the necessary funds.* If the Government, particularly in view of its 1942 model of economy, cannot recognize the investment value of a medical student, when physicians are needed so badly, it had better revamp the Selective Service System. Actually, the Government does appreciate the value not only of the medical student but also of the premedical student, and medical schools and colleges could make no better investment than to stake their needy students at a low rate of interest.

(3) *Prescribed R.O.T.C. field training must*

*be discontinued.* If the R.O.T.C. cannot accommodate themselves to anything other than "business as usual," they are overlooking their own interests and responsibilities in the urgency of the moment.

(4) *The technical and teaching staffs must be greatly increased or must devote far more time to their work.* Each medical school must, of course, decide what it is able to do. So far, there has been little, if any, complaint of overwork from the staffs of schools that have adopted the shortened schedule. Furthermore, the medical schools that remain on the old schedule will be a convenience to those college students who cannot complete their premedical requirements until September.

(5) *Unless colleges and hospitals have their curriculums suitably integrated with those of medical schools, the students will lose three to six months waiting for admission as medical students or as interns.* Such a condition has always existed, and there seems to be little necessity of adding another three months each year in the summer.

That professional standards must be lessened is undeniable and inevitable. They have already been lowered by the reduction of internships to one year, and by the renunciation of the somewhat grandiose thought, recently developed, that it takes six or eight years of hospital residence to make a surgeon. To protect the premedical student, it may be necessary to trim medical-school requirements. Physicians with teaching positions will have more work to do, in addition to that already demanded by plans for air-raid protection and civilian defense. Only time can be saved now. Yesterday's leisurely standards must be abandoned. Perhaps the emergency is a little more real and vivid to those who live along the seacoasts than to those in Chicago.

### MEDICAL EPONYM

#### MILROY'S DISEASE

William Forsyth Milroy (b. 1855), professor of clinical medicine and hygiene in the Omaha (Nebraska) Medical College, read a paper entitled "An Undescribed Variety of Hereditary Oedema"

before the Society of the Alumni of Charity Hospital on June 1, 1892; this was published in the *New York Medical Journal* (56: 505-508, 1892). He described the condition as follows

On August 20, 1891, Mr H presented himself for examination for life insurance. The applicant called my attention to his lower extremities. I found a condition of oedema involving the feet and extending up the legs to the knees. Upon inspection the leg presented a slightly rosy hue. Scattered thickly over this base were white spots about the size of a pea. Mr H stated that this oedematous enlargement had existed from birth, that this enlargement of the extremities was a family characteristic which he had inherited from his mother. Fortunately for the purpose of this study, in 1883 a member of the family published a neat volume, giving the family history in America for a period of two hundred and thirty years. The peculiarity now under discussion seems to have entered the family by marriage about 1768. With the aid of this volume and the assistance of members of the family still living, I am able to offer the facts which I present.

1 So far as known, in every case, with two exceptions only, the oedema was present at birth.

2 The location of the oedema has in every case been limited to one or both lower extremities.

3 The presence of the oedema is persistent, never having been known to disappear, temporarily or permanently, except in one instance.

4 It has never been attended by constitutional symptoms, barring the two possible cases in which its first appearance was subsequent to birth.

From these considerations it seems evident that the case under discussion is not one of angio-neurotic oedema. Whether or not the case is one of nervous edema, it is offered that, with others, sufficient material may be accumulated to render possible study of these unusual forms of oedema.

### COMMITTEE ON MATERNAL WELFARE

#### CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1940 (continued)

##### RUPTURE OF UTERUS

One case in which autopsy was performed and a diagnosis of ruptured uterus established was an example of very poor obstetrics. An attempt to deliver the patient at home had been made by her physician, and when she arrived in the hospital, her pulse was 130 and she was in shock. The physician had diagnosed a prolapsed arm, and a version had been unsuccessful. A Braxton-Hicks maneuver was performed shortly after entry, and delivery was completed several hours later, with craniotomy of the after coming head.

The rupture of the uterus was not diagnosed; had it been appreciated, laparotomy with probable hysterectomy might well have saved this patient's life.

Another patient with a ruptured uterus died on the table, undelivered. Forceps delivery had been attempted, and version had been tried unsuccessfully before death. Post mortem examination revealed a rupture of the lower segment. Such a death is inexcusable.

Another case of ruptured uterus occurred in association with a partial placenta previa. Version was done, and the patient, while on the table, went into profound collapse and died six hours later. Although no autopsy was performed, this was undoubtedly a case of ruptured uterus.

The next case of ruptured uterus was associated with an abnormal fetus and operative delivery. To deliver the fetus, craniotomy was necessary. During the process, the patient rapidly failed and died one hour after she was delivered. No x-ray film had been taken in this case to determine the size of the fetus, and this death can be attributed only to poor obstetrics.

One case was associated with a long-drawn-out, poorly handled labor. Three ½ ampule doses of pituitary extract were given during labor. The patient died very soon after a difficult forceps delivery. There is no excuse for this death.

In the next case, which was associated with a previous cesarean section, the patient went into spontaneous labor, and the uterus ruptured before she was delivered. Autopsy confirmed the diagnosis.

In the second case with a previous cesarean section, the patient died of a rupture of the uterus during labor. This case was poorly handled throughout.

Another patient, who had had five previous cesarean sections, was in the hospital thirty six hours before operation. Low cervical section was performed, and the patient's condition is said to have been excellent. Six hours later, she went into profound shock and died after four hours. Autopsy showed that the rupture occurred in conjunction with an old scar. The incision of the present operation was intact. This death is hard to explain.

Of these 8 cases,\* 3 were associated with previous cesarean section. This fact emphasizes the seriousness of the initial section, and certainly proves that scars of previous cesarean sections may

\*Further study of the cases of maternal death in 1940 has necessitated a change in the classification of the cause of death in several. Hence the total numbers of cases in many of the groups do not agree with those given in the table in the January 8 issue of the *Journal*. A corrected table will be published in a subsequent issue.

rupture. The last case mentioned, in which an autopsy showed the rupture quite separate from the new incision, is most illuminating as well as very unusual. Those cases of ruptured uterus associated with operating are all examples of very poor obstetrics. These can never be eliminated until obstetrics is more carefully supervised in all obstetric hospitals.

#### ECTOPIC PREGNANCY

Six cases of ectopic pregnancy, 5 tubal and 1 abdominal, resulted fatally.

One patient with tubal pregnancy was operated on five hours after the onset of acute symptoms. Much free blood was found in the abdomen. This patient died of peritonitis, five days after operation.

Another case, which was viewed by the medical examiner and in which no autopsy was performed, was undoubtedly one of exsanguination due to rupture in tubal pregnancy. The patient was not operated on, and the immediate history was not available. She was dead when she reached the hospital.

One patient died during operation. It is quite possible that spinal anesthesia was the primary cause of death, since the operation was begun within a short time of the onset of symptoms, when the patient was said to have been in good condition.

Another patient reached the hospital with a blood pressure of only sixty. This patient died without operation. No transfusion was given.

One patient died, not of the tubal pregnancy but of some pulmonary complication, five weeks subsequently.

There was 1 case of abdominal pregnancy, discovered at autopsy. The diagnosis was entirely missed, and the death was surely avoidable.

#### SURGICAL SHOCK

In 4 cases, the patients died very shortly after cesarean section, and hemorrhage did not seem to be the prime cause of death; hence, they are classified as due to surgical shock. In 1 of these cases, attempts at forceps delivery and version had failed, and in 1 case, a classic cesarean section was performed by a general surgeon. There is nothing to add about the other 2 cases, except that they, too, were badly handled.

One patient was operated on for a retained placenta previa. The history makes little mention of hemorrhage, so that death must be attributed to shock. Autopsy revealed that the uterus was not ruptured, and that a placenta accreta existed. The diagnosis of placenta accreta, of course, should

have been made before death. Had this diagnosis been made, transfusion and hysterectomy might well have prevented this death.

#### SURGICAL DISEASES

*Acute appendicitis.* Three cases of acute appendicitis resulted fatally.

One patient was between five and six months pregnant. The appendix had ruptured before the operation, and the patient died of general peritonitis five days later.

Another patient—about six months pregnant—who was operated on for acute appendicitis aborted eight days after operation. Her condition grew worse, and she died seventeen days after operation.

Another case of acute appendicitis occurred in a patient who was six months pregnant. At operation, the appendix was gangrenous; free pus was found in the abdomen, and the patient died on the fifth day after operation. She aborted spontaneously just before death.

It is very difficult to state that any of these deaths might have been prevented, but if they were under a physician's care from the onset and not diagnosed until after peritonitis developed, the physician certainly should be considered culpable.

*Intestinal obstruction.* One patient was operated on for acute intestinal obstruction, which autopsy proved to be due to adhesions that had followed a gastroenterostomy. This patient was about six months pregnant, and as a last resort, four days before death, delivery was induced. This procedure certainly cannot, in any way, be condoned.

Another patient, who was four and a half months pregnant, died of intestinal obstruction. At operation, it was found that the obstruction was due to adhesions from a previous operation.

One patient, when about seven months pregnant, entered the hospital with a history of having vomited for a few days, with a great deal of abdominal pain. An operation for intestinal obstruction was performed, and at the same time, cesarean section was done. The patient failed, and died of complete intestinal obstruction. If intestinal obstruction demands operation, the uterus should be left alone.

In another case, the patient was about four and a half months pregnant and was under observation at the hospital for five days before the diagnosis of intestinal obstruction was made. This patient aborted shortly before death. Intestinal obstruction was due to adhesions from previous

operations The operation to relieve the obstruction was undertaken too late to be of any value.

It should be axiomatic, in all cases of intestinal obstruction that occur during pregnancy, that the pregnancy be disregarded and that the obstruction be treated; the sooner the operation is performed, the greater the likelihood of recovery. It certainly is a reflection on the medical profession of Massachusetts to allow a patient to remain in the hospital five days before diagnosis and operation, as was true in one of these cases.

## DEATHS

**DOWNEY**—**HUGH J. DOWNEY**, M.D. of Pittsfield died January 31. He was in his sixtieth year.

Born in Adams, Dr. Downey received his degree from Chicago College of Medicine and Surgery in 1912. He was a former secretary and president of the Berkshire District Medical Society. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a son and a daughter survive him.

**POTTER**—**A. CARLETON POTTER**, M.D., of Cambridge, died January 28. He was in his sixty-ninth year.

A native of Cambridge, Dr. Potter received his degree from Harvard Medical School in 1899. At the time of his death he was president of the New England Society of Physical Medicine, and was a fellow of the Massachusetts Medical Society and the American Medical Association.

His widow, a daughter and a sister survive him.

**WEISS**—**SOMMA WEISS**, M.D., of Boston, died January 31. He was in his forty-fourth year.

Born in Hungary, Dr. Weiss received his degree from Cornell University Medical College in 1923. He was assistant at the Thorndike Memorial Laboratory from 1925 to 1929, assistant in medicine at Harvard Medical School from 1926 to 1927, instructor from 1927 to 1929, assistant professor from 1929 to 1932 and associate professor from 1932 to 1939, he was appointed Hersey Professor of the Theory and Practice of Physics in 1939. He was assistant director of the Thorndike Memorial Laboratory from 1930 to 1932, director of the Second and Fourth Medical Services (Harvard) of the Boston City Hospital from 1932 to 1939, and physician in chief of the Fourth Medical Service from 1936 to 1939. He was named physician in chief of the Peter Bent Brigham Hospital in 1938. He was a fellow of the American College of Physicians, the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow and three children.

## WAR ACTIVITIES

### UNITED STATES NAVY

The following medical officers of the United States Naval Reserve have been assigned to active duty in the First Naval District:

Adams, J. F., Lieut. (JG)  
Agnew, J. G., Lieut. Comdr.  
Allman, C. H., Lieut. Comdr.

Alt, R. E., Lieut.  
Apollonio, H. L., Lieut.  
Armitage, H. G., Lieut. Comdr.  
Atkins, H. T., Lieut. (JG)  
Atkinson, G. D., Lieut. Comdr.

Bakst, H. J., Lieut.  
Balch, F. G., Lieut. Comdr.  
Barr, J. S., Lieut. Comdr.  
Benjamin, L. B., Lieut.  
Brown, B. F., Lieut. Comdr.  
Buddington, W. T., Lieut.  
Burrage, W. S., Lieut. Comdr.

Carmody, J. T. B., Lieut.  
Carr, F. B., Lieut. Comdr.  
Carson, P. C., Lieut.  
Cristen, V. G., Lieut. Comdr.  
Chancey, D. J., Lieut.  
Clapp, W. B., Lieut.  
Coffin, W. K., Comdr.  
Cordray, D. P., Lieut.  
Crandon, J. H., Lieut. (JG).

Daniels, D. H., Lieut.  
Davidson, W. B., Lieut. Comdr.  
Dawson, W. E., Lieut. (JG)  
Dement, D. E., Lieut. Comdr.  
Derow, S., Lieut.  
Di Cicco, L. M., Lieut. Comdr.  
Doyle, J. B., Lieut. (JG)  
Drake, E. H., Lieut. Comdr.  
Draper, R. T., Lieut. Comdr.  
Duncombe, A. L., Lieut.

Eley, R. C., Lieut. Comdr.

Faulkner, J. M., Lieut. Comdr.  
Faunce, C. B., Comdr.  
Fay, J. H., Lieut. Comdr.

#### OPPORTUNITY FOR APPOINTMENTS OF PREMEDICAL AND MEDICAL STUDENTS AS ENSIGNS H-V(P), UNITED STATES NAVAL RESERVE

The Secretary of the Navy recently approved a change in Navy regulations whereby it is now possible for those premedical students who have been accepted for entrance to, and all medical students in, Class A medical colleges to be appointed in the United States Naval Reserve in Class H-V(P), provided they meet the physical and other requirements for such appointment.

Students who are acceptable will be given provisional commissions as ensigns, and it is the policy of the Bureau of Medicine and Surgery not to nominate such officers for active duty until after they have completed their prescribed medical studies and shall have served one year's satisfactory internship in a civilian hospital accredited for intern training, or shall have been accepted as acting assistant surgeons in the Navy for intern training.

On graduation, and when the bureau has been informed of this fact by the dean, commissions as Lieutenant (JG) MC-V(G), United States Naval Reserve, will be issued to provisional ensigns and, after serving their internship in non-naval hospitals, they will be nominated for active duty. Application for, or acceptance of, either a provisional or permanent commission in the Naval Reserve, does not preclude the possibility of applying for a commission in the Medical Corps of the Navy. Persons affiliated with the Naval Reserve are not subject to induction into Army service by action of local Selective Service boards.

Navy regulations require that all applications for appointments in the Naval Reserve be filed with the commandant of the naval district in which the applicant resides. The address of the commandant in each district may be obtained from the dean of the medical college.

Application forms may be obtained from the dean's office or from someone designated by him, on request from the Bureau of Medicine and Surgery, Navy Department, Washington, D. C., or from the commandants of naval districts. When an application form has been properly completed, it, together with the other credentials indicated on the application form, should be mailed to the commandant of the naval district. He will issue instructions for obtaining a physical examination, fingerprints and so forth.

A premedical student must enclose with his application for appointment a statement, signed by the dean of a medical college, to the effect that the applicant has been accepted as a first-year medical student in a Class A school for the next entering class.

It is the understanding of the Bureau of Medicine and Surgery that Selective Service boards will accept a statement from the commandant of any naval district, to the effect that an application is on file, as basis for deferment until the application has received final action.

#### REPORT OF MEETING

##### NEW ENGLAND PATHOLOGICAL SOCIETY

The following report of the Executive Committee was presented at a business meeting of the New England Pathological Society on January 13, 1942. The report was accepted, and the recommendations adopted.

\* \* \*

##### RECOMMENDATIONS OF THE EXECUTIVE COMMITTEE CONCERNING THE STATUS OF PATHOLOGISTS DURING THE WAR EMERGENCY

Maximal war effort requires the maintenance of normal standards of health in the civilian population, and an in-

escapable corollary is the continued efficient conduct of civilian hospitals. The inevitable transfer of medical, nursing and technical personnel to military service and of labor to both industry and military service will make this difficult. A more specific danger is the potential loss of certain highly trained specialists, relatively few in number, who are essential to modern hospital practice. Pathologists and roentgenologists are obvious examples. Even in prewar conditions, the supply was inadequate. Many will certainly be required for both the Army and Navy and all hospitals will be left either understaffed or completely desolate unless a skeleton group of reasonable dimensions is maintained in each locality and is so organized that its efforts may be rendered most efficient. In an effort to formulate plans for meeting this prospective emergency, the Executive Committee of the New England Pathological Society proposes the following suggestions for consideration.

At the present moment, only general principles can profitably be outlined. Specific recommendations must await more precise definition of the problem and depend on the number of pathologists drawn into the services and on the number, size and location of the hospitals in need of aid. It is to be noted that the situation differs essentially from that which existed in World War I, since at that time, few of the small or community hospitals had pathological laboratories. It is to be hoped that few hospitals under the pretext of economy will revert to the standards of twenty years ago.

Certain premises can be laid down.

(1) Pathologists must be maintained in the larger metropolitan hospitals and in the departments of pathology of the medical schools, to provide for the accelerated medical curriculum. Administrative officers of schools and of hospitals fortunate enough to maintain a pathological staff should be approached, and their co-operation enlisted in solving the needs of the larger communities.

(2) Although much unessential work is demanded of laboratories in ordinary times that can and should be largely eliminated, an irreducible minimum of diagnostic laboratory procedures exists and must be maintained.

(3) Two methods for maintaining this minimum are available.

(a) To send the material by mail or messenger to central laboratories where pathologists must be maintained, such as the laboratories of the large metropolitan hospitals, the laboratories of the medical schools and the small laboratories where a pathologist is still on service, including private laboratories.

(b) To carry out the technical work locally and arrange a consultative service by which a pathologist will visit at regular intervals to make histologic diagnoses and to supervise and check the technical staff, and by appointment will respond for frozen section diagnoses and autopsies.

Plan (b) service, although obviously preferable, will be much more difficult to maintain. Only a limited number of hospitals can be so provided for, and these must have adequately equipped and staffed laboratories and must be within a limited geographic area in relation to a central laboratory.

In arranging contracts with hospitals, the following principles should be borne in mind.

(1) It should be assumed that all pathologists called to military service are on leave of absence from their respective posts. Therefore, all contracts of consulting pathologists must be terminable with the return of the original pathologist to civilian life.

(2) The hospitals must pay the cost of services rendered. Under Plan (a), this may appropriately be calculated according to the scale of charges authorized by the New England Pathological Society. It is preferable that the fees be paid directly to the pathologist assuming the work and that he, in turn, adjust with his primary employer for the costs of supplies increased technical and secretarial services and so forth. Under Plan (b), the consulting pathologist should receive compensation in the form of a salary proportionate to the work and time involved. The consulting pathologist should not allow the newly assumed duties to cut seriously into the time paid for by his primary employer without negotiating a reasonable adjustment in salary.

(3) The consulting services so offered must fall significantly short of the full service of a pathologist to his hospital. Minimum diagnostic requirements will be met, but the intangible values of constant availability for consultation, for minor administrative tasks and so forth must be sacrificed. It should be possible so to adjust the cost of this limited service that the hospital may, without increased expense, make up to its pathologist in service an approximate difference between his former civilian and his present military salary.

It is proposed that the New England Pathological Society set up a group of regional committees from which any member who expects to enter military service may seek advice concerning his individual problem, and to which hospitals in need of pathological services may apply.

\* \* \*

Subsequent to the meeting, the following regional chairmen were appointed:

*Eastern Massachusetts* Dr Tracy B Mallory  
Massachusetts General Hospital, Boston

*Western Massachusetts* Dr J S Beck  
Memorial Hospital, Worcester

*Maine* Dr Mortimer Warren  
Maine General Hospital, Portland

*New Hampshire and Vermont* Dr Ralph Miller  
Dartmouth Medical School, Hanover, New Hampshire.

*Rhode Island* Dr B Earl Clark  
Rhode Island General Hospital, Providence

*Connecticut* Dr Harry M Zimmerman  
Yale University, School of Medicine, New Haven

## BOOK REVIEWS

*Bacillary and Rickettsial Infections, Acute and Chronic. A textbook—black death to white plague.* By William H Holmes, MD. 8°, cloth, 675 pp. New York: Macmillan Company, 1940. \$6.00.

Before the early part of the nineteenth century at least, no man who undertook the discussion of a particular disease failed to include something of its history. Dr Holmes has resumed that valuable and interesting prac-

tice for each of the maladies with which he deals. Without it, he would still have written an excellent and trustworthy book, for his discussion of etiology, epidemiology, diagnosis, treatment and prevention leaves little to be desired. With it, he has achieved something that for a modern textbook is almost unique. The classic descriptions, of which there are many, are to be cherished. Specifically the maladies considered are plague, tularemia, the rickettsial infections of man, undulant fever, cholera, typhoid and paratyphoid fevers, the bacillary dysenteries, diphtheria, botulism, tetanus, gas gangrene, pertussis, the hemophilic infections, leprosy, tuberculosis, sarcoidosis and the rarer bacillary infections—anthrax, glanders and the like (considered together in a final chapter). The various sections are closed with adequate bibliographies.

One might add that the book is of convenient size and weight and is delightfully printed. It should be a welcome book for anyone whose practice embraces its matters.

*A Research Conference on the Cause and Prevention of Dental Caries.* Chicago, Illinois. July 1 and 2, 1938. Sponsored by The Good Teeth Council for Children, Incorporated. 8°, cloth, 178 pp., with 11 figures, 12 tables, 6 charts and 6 graphs. Chicago: Good Teeth Council for Children, Incorporated, 1940. \$2.00.

In this small volume, reports of research on dental caries by twelve nationally known investigators are assembled, together with discussions by other research workers. The wit and wisdom of Dr. E. V. McCollum, of Johns Hopkins University, who was the moderator of the conference, illuminate the text.

Of the many factors that may be involved in the etiology of dental caries, five are presented in this volume: the morphology of the teeth, the composition of the saliva, the role of vitamin D, age incidence and the flora of the mouth.

The reports and discussions indicate the complexity of the problem of dental caries but bring out quite clearly the directions being taken by these investigators in their search for new knowledge. The anatomic, chemical and bacteriologic background of dental caries is thoroughly discussed.

For those engaged in any phase of research in dental caries, this book should be a valuable reference volume.

*The Endocrine Function of Iodine.* By William T. Salter, M.D. 8°, cloth, 351 pp., with 45 tables and 40 illustrations. Cambridge, Massachusetts: Harvard University Press, 1940. \$3.50.

This is the first of the current series of Harvard University monographs in medicine and public health. The author, now professor of pharmacology at Yale University, has worked with Harington in England on the chemistry of the thyroid gland; with Means and the clinical group at the Massachusetts General Hospital; and at the time of writing, as both clinician and biochemist at the Thorndike Memorial Laboratory of the Boston City Hospital. He is, therefore, well qualified to present a broad view of the subject.

The book does not give a systematic or exhaustive discussion of the thyroid gland, but takes as its point of departure the nature and functions of body iodine, surveying the thyroid and other endocrines only from the standpoint of iodine. This gives in some ways a rather disconnected story; on the other hand, it brings together for the first time all the available studies of iodine in body economy and endocrine balance, and leaves to the textbooks the conventional approach to the thyroid gland and its disease.

The early chapters review the iodine content of all the body tissues and organs, and of the blood and body fluids. The new technics for determining plasma iodine and its fractions have been of great value. There is a discussion of important iodine-containing compounds, such as thyroglobulin, di-iodotyrosine and thyroxine. Then follows a consideration of the role of iodine in thyroid activity, in relation to the pituitary gland and its thyrotropic hormone, and in the interactions of the pituitary and thyroid glands and the gonads. The newer work on iodine balance is presented at some length, and there is a most interesting discussion of radioactive iodine and its recent uses in the study of iodine metabolism by following "tagged atoms" of radioactive isotopes.

Of interest to clinicians is a chapter on clinical problems, in which ten selected cases are cited to show the application of such new diagnostic aids as total-plasma iodine, the "P" and "T" plasma-iodine fractions and the fecal iodine excretion. One is impressed with the need for meticulous control of all conditions in making these tests, and for caution in their interpretation.

There is an appendix for laboratory workers, in which significant new technics are set forth in detail. An exhaustive bibliography adds greatly to the value of the work.

*The Pharmacological Basis of Therapeutics: A textbook of pharmacology, toxicology and therapeutics for physicians and medical students.* By Louis Goodman, M.D., and Alfred Gilman, Ph.D. 4°, cloth, 1383 pp., with 126 illustrations and 67 tables. New York: The Macmillan Company, 1941. \$12.50.

This large volume covers the pharmacology, toxicology and therapeutics of practically all the drugs now in common use. It is an extraordinary compilation—clear, detailed, accurate, well documented, adequately illustrated and superbly indexed. No book in recent years has so appealed to the reviewer as a fundamental contribution, finely executed. Although the price is not low, the book is well worth its cost. It should be in every medical library and research center, and would be a valuable addition to many physicians in their private libraries. The book will constantly be referred to by any doctor who attempts to keep up with modern trends, and its value to the scientific investigator is great.

The volume is excellently published; the paper is light, but adequate, the illustrations are clear, and the bibliography is easy to read.

*A Textbook of Dietetics.* By L. S. P. Davidson, B.A. (Cantab.), M.D. (Edin.), F.R.C.P. (Edin. and Lond.), F.R.S.E. and Ian A. Anderson, M.B., Ch.B. (Aberd.). With diet sheets constructed by Miss Mary E. Thomson, S.R.N., and a foreword by Sir John Boyd Orr, M.D., D.Sc., LL.D., F.R.S. 8°, cloth, 324 pp., with 27 tables. New York: Paul B. Hoeber, Incorporated, 1941. \$4.25.

The problem of nourishment in some form or other has always occupied the attention of man. This has now become a mass problem because of widespread economic and social dislocations. The introduction of more commercial methods of food preparation is also a source of abnormal nutrition. It is incumbent on every physician to be conversant with a knowledge of dietetics, which is applicable to the recognition of late and frank cases of vitamin deficiencies, problems of malnutrition and obesity and the care of specific metabolic diseases. This book can be regarded as an adequate introduction to the subject. Unfortunately, since it is a British publication, many preparations are mentioned that are unfamiliar to Americans, and the difference in dietary habits is noteworthy. Both considerations lessen the value of the book for Americans.

## THE DIAGNOSIS OF CORONARY-ARTERY DISEASE\*

H M MARVIN, MD†

NEW HAVEN, CONNECTICUT

IT IS surely unnecessary to remind an audience composed of physicians that the many factors that may enter into the diagnosis of coronary artery disease cannot possibly be discussed in any adequate or comprehensive fashion in the space of a few minutes, or indeed of a few hours. I am sure that I shall be forgiven if I attempt to present in abbreviated and almost tabular form a few of the more important established facts relating to this condition. Any appearance of dogmatism or unjustified authority in my statements is due solely to limitations of time, which do not permit the discussion of controversial points or the presentation of opposing evidence.

The term "coronary-artery disease" so widely used today includes all known varieties of change in these vessels, and some of them are so infrequent or of such slight clinical interest as to justify their exclusion. In general, ability to recognize disease of the coronary arteries is restricted to conditions that interfere with the nutrition of the myocardium sufficiently to cause symptoms, changes in the x-ray film or alterations in the electrocardiogram. Changes of this degree are usually due to arteriosclerosis, with narrowing or closure of coronary branches, and I interpret the term "coronary-artery disease" to mean coronary arteriosclerosis for the purposes of this discussion. And the question that I shall attempt to answer, in part, is, What criteria will enable one to suspect, or to recognize with certainty, structural changes in the coronary arteries that interfere with the heart's nutrition sufficiently to be of consequence to the patient?

### Clinical Evidence

There is now complete agreement among authorities that the presence of typical and unmistakable anginal pain should be regarded as evidence that the coronary blood flow is inadequate for the needs of the heart muscle, and that this inadequacy is due in most cases to arteriosclerotic narrowing or closure of the vessels, although typical anginal pain may occur in the presence of normal coronary arteries in cases of severe anemia or during prolonged paroxysms of tachycardia with excessive ventricular rates. It may also occur in the absence of coronary arteriosclerosis in occasional cases of hyperthyroidism, or in patients whose hearts are greatly enlarged as a result of hypertension or rheumatic disease of the aortic valves, presumably because the increased demands of the hypertrophied myocardium for blood are not met by a corresponding increase in the coronary blood flow.

The question that immediately arises is, What is typical and unmistakable angina? Most cardiologists frequently encounter patients whose physicians have assured them that they have angina pectoris, when a careful analysis of their symptoms reveals that they do not. The diagnosis of angina is based, with one possible exception, exclusively on the history given by the patient, and not in any degree on the physical or x-ray examination, or the electrocardiogram. And the history that compels a diagnosis of angina includes among its more significant features the following: the discomfort in the chest is dull, squeezing or constricting, never sharp or knifelike, it occurs usually beneath the sternum, and not over the body of the heart; if it radiates, it is almost always to the shoulder and down the inner aspect of the arm, more frequently the left; the discomfort is of brief duration, usually from half a minute to three or four minutes; it is constant from the moment of onset until its complete disappearance—that is, it does not come and go, or wax and wane in intensity, for periods of seconds; it has a close rela-

\*Presented at the New England Postgraduate Assembly, Cambridge, Massachusetts, October 30, 1941.

†Associate clinical professor of medicine, Yale University School of Medicine, and attending physician, New Haven Hospital.

the T wave may disappear if the curve is recorded during deep inspiration or while the subject stands erect. Both the deep Q and the inverted T waves may remain for many years without change and without the appearance of any signs of heart disease. I have little hesitation, therefore, in expressing the opinion that it is unjustifiable and even deplorable to interpret a deep Q wave in Lead 3 by itself as an indication of heart disease, and especially as a specific sign of coronary sclerosis.

And, finally, I come to that portion of the curve that has caused greater trouble than all others combined: the ST segment and T wave. I cannot discuss this in the detail that it merits. Depression or elevation of the ST junction or segment and inversion of the T wave are apparently more generally accepted than any other changes in the electrocardiogram as indications of heart disease, and especially of coronary arteriosclerosis. Whether or not this statement is justified can be judged by the following quotation from a recent article by Sprague<sup>5</sup>:

Without the hope of its being complete, the following list of conditions, other than coronary atherosclerosis, responsible for abnormalities of S-T and T segments is submitted:

- |                         |                          |

| d. Dissecting aneu-    | tion of ice water     |
| rysm of corona-        | k. Terminal states of |
| ry artery              | all kinds             |
| e. Dissecting aneu-    | l. Unexplained        |
| rysm of aorta          |                       |

This list contains forty-one different conditions, thirty-three of which do not imply heart disease!

I do not wish to imply that coronary atherosclerosis does not cause changes in the ST segments and T waves, because undoubtedly it does. But I do wish to state emphatically that coronary disease is only one of many factors that cause such changes, and it is impossible to decide from the electrocardiogram alone which of these many causes is responsible. One might just as well attempt to make a correct and specific diagnosis of disease on the sole basis of slight leukocytosis, without any knowledge of the clinical picture and other laboratory tests.

I think that this whole matter may be summarized in one sentence. If myocardial infarction is excluded, *there is no change in the electrocardiogram that in itself justifies the diagnosis of coronary disease*, because the alterations on which this diagnosis is based may be—and often are—due to other causes. I am in the heartiest agreement with Wilson<sup>6</sup> when he says, "It would be better if this term [coronary disease] were never used under any circumstances in connection with the interpretation of the electrocardiogram."

303 Whitney Avenue

just described, a condition of simple vaginal hydrocele (ordinary hydrocele) exists. This is shown in Figure 2A by a diagram similar to those of Jacobson<sup>18</sup> and Campbell.<sup>24</sup> If the distal portion of the stalk of the processus vaginalis fails to be-

the processus vaginalis becomes obliterated for only a very short distance at the level of the internal inguinal ring, and if a large amount of hydrocele fluid accumulates, further stretching of the sac toward the abdomen can occur, producing

FIGURE 2. *Diagrams of Several Types of Hydrocele.*

A.—*Simple or vaginal hydrocele*; B.—*infantile hydrocele*, C.—*abdominoscrotal hydrocele*. Abbreviations: P.—*peritoneum*; E.—*epididymis*; T.—*testis*; I.R.—*internal inguinal ring*; E.R.—*external inguinal ring*; O.P.V.—*obliterated processus vaginalis*; C.T.V.—*cavity tunica vaginalis*.

come obliterated, so that the cavity of the tunica vaginalis extends upward to the level of the inguinal canal instead of to a point just above the

the condition known as abdominoscrotal hydrocele (Fig. 2C).

Several different theories have been held regarding the development of abdominoscrotal hydrocele and its relation to the peritoneum. Dupuytren<sup>1</sup> believed that with extreme distention the ordinary vaginal hydrocele could push its way up through the inguinal canal and assume an abdominal position. Kocher<sup>14, 15</sup> shared this view. Against the views of Dupuytren and Kocher may be cited the numerous cases of ordinary hydrocele in which the fluid is confined under considerable pressure, without extension beyond the confines of the simple vaginal hydrocele. Probably, the more logical explanation—expressed by Jacobson,<sup>18</sup> Macewen<sup>25</sup> and Tanzer,<sup>26</sup> with whom I agree—is that a persistent type of high infantile hydrocele exists in which the processus vaginalis is obliterated only at the level of the internal ring. If distention of the upper portion of the sac occurs, there are no confining structures on the posterior or peritoneal aspect to limit the abdominal expansion. As Tanzer has stated, the abdominal sac can be considered an evagination from the proximal end of the hydrocele sac (Fig. 2C).

FIGURE 3. *Drawing of the Infantile Type of Hydrocele (Bazy<sup>16</sup>).*

testis, and if that cavity becomes filled with fluid, there exists, as originally outlined by Jacobson, an infantile type of hydrocele (Figs. 2B and 3). If

The relation of the sac to the peritoneum and the abdominal wall deserves discussion. From the case reports, it becomes obvious that several types of abdominoscrotal hydrocele exist. In fact, Delbet,<sup>27</sup> in 1896, proposed that they be divided into properitoneal, interstitial and superficial types, on

FIGURE 4. Diagram of Layers of the Abdominal Wall and Peritoneum and Their Relation to an Abdominal Hydrocele (Bazy<sup>16</sup>).

Abbreviations: P.A.—abdominal wall; P.P.A.—peritoneum covering abdominal wall; P.I.—peritoneum covering iliac fossa, compressed by tumor; Pa.H.—wall of hydrocele; S.H.—scrotal portion of hydrocele; A.H.—abdominal portion of hydrocele; P.H.—pelvic portion of hydrocele; A.F.—femoral arch; C.S.P.—peritoneal cul-de-sac; T.—testicle.

the basis of the relation to the abdominal wall. To make this classification complete, one should add the retroperitoneal type. Bazy believed that there were two layers of peritoneum between the abdominal wall and the hydrocele sac (Fig. 4) and Lister,<sup>8</sup> after a post-mortem dissection on a case, declared that "it formed a tumor beneath the peritoneum lying in the iliac fossa and the lower part of the anterior wall of the abdomen." Coleman<sup>28</sup> also considered his case to be of the retroperitoneal type. On the other hand, Delbet believed that his case was of the superficial type, the sac lying superficial to the muscles of the abdominal wall. The majority of cases are, I believe, of the properitoneal type, in which the abdominal portion of the sac lies between the muscles of the abdominal wall and the peritoneum (Fig. 5).

The clinical aspects of abdominoscrotal hydrocele are of interest since the occurrence is relatively uncommon, and most communications on the subject consist of single case reports.<sup>29-40</sup> Some of the present-day texts on urology fail to mention the condition, although others<sup>41, 42</sup> briefly describe it. If Brandenburg<sup>43</sup> is correct in estimating the cases collected up to 1921, there have now been about 53 reported cases (including the one described in this paper)

The majority of patients were in the second or third decade of life when they sought treatment, although Kocher reported cases in children one and thirteen years old, and Syme<sup>44</sup> reported a case in a four-year-old child. The oldest men described in the case reports were the fifty-four-year-old patient of Fuchs<sup>9</sup> and the fifty-five-year-old patient of Wettergren.<sup>45</sup>

Both right and left scrotal regions have been affected and with approximately equal frequency. The history is usually that of a painless swelling developing first in the scrotal region and later extending to the groin and abdomen. Many patients are apparently not inconvenienced by the large abdominal protrusion that develops, although Steele's<sup>10</sup> patient complained of difficulty in walking. However, the symptoms in Steele's case may have been due to the pressure on an undescended testis rather than to the abdominal swelling per se.

Physical examination discloses not only the scrotal swelling but an abdominal tumor that can

FIGURE 5. Diagram of the Relation of the Peritoneum and Abdominal Muscles to an Abdominoscrotal Hydrocele.

Abbreviations: A.M.—abdominal muscles; P.—peritoneum; C.T.V.—cavity of tunica vaginalis; I.—level of inguinal ligament; S.—scrotal wall; T.—testis and epididymis.

reach large proportions. It is not unusual to find the abdominal protrusion, the size of a six or seven months' gravid uterus, extending above the level of the umbilicus and beyond the midline. The tumor is smooth, firm, nontender and flat to percussion. The scrotal tumor transilluminates well unless the sac contains blood. Pressure on the abdominal portion of the sac creates a fluid wave or thrill to the scrotal area. Usually, coughing creates a definite impulse in the scrotal region, a phenomenon similar to the fluid wave produced by sudden compression of the abdominal portion of the sac. Occasionally, the abdominal swelling is extensive enough to give the impression of ascites. Catheterization of the bladder obviously fails

to reduce the size of the tumor. In the pelvic type of abdominoscrotal hydrocele, rectal examination should disclose a ballotable pelvic mass continuous with the scrotal swelling. Holmes<sup>21</sup> injected 60 cc. (2 ounces) of saturated sodium iodide into the scrotal sac before operating, and obtained a graphic picture of the large abdominoscrotal sac. It is evident that the diagnosis is not difficult so long as one realizes that such a condition exists.

Several different forms of treatment have been used. They may be grouped in three divisions: puncture, incision and drainage, and excision.

In 1860, Rochard<sup>46</sup> found it necessary to incise and drain a hematocele sac of 2940 cc. after the injection of iodine had been unsuccessful in the treatment of the condition. In 1875, Steele<sup>10</sup> tapped and withdrew 900 cc. (30 ounces); he then allowed infection to occur, hoping to obliterate the cavity by this method, and the incisions finally healed. Trendelenburg<sup>11</sup> likewise used incision and drainage. Kocher employed puncture in 2 children and followed the procedure by the injection of tincture of iodine in 1; phlegmon of the scrotum developed in 1 of these cases. Witzel<sup>13</sup> used for drainage a groin incision rather than one over the scrotum. In 1896, Mikulicz performed a radical operation (excision) in the case reported by Vollbrecht.<sup>4</sup> Von Winiwarter,<sup>5</sup> in 1899, also found it necessary to excise a sac that had refilled following treatment by puncture. To ensure drainage, Bickle<sup>20</sup> stitched the edges of the sac to the skin edges. Excision has come to be the accepted procedure for permanent relief. Tapping is frequently followed by recurrence within a few months and, infrequently, by infection, which creates a surgical emergency. Incision is followed by a long period of drainage and is often complicated by infection.

Although the operative technic of excision can be very easy, certain writers have reported difficulties. Coleman<sup>28</sup> found it advisable to use a scrotal and an abdominal incision. Lasbrey<sup>22</sup> believed the sac to be retroperitoneal, and he used two incisions; there was some difficulty in removing the sac. Curtis,<sup>47</sup> who experienced difficulty with a laparotomy incision, was nevertheless able to complete the operation through a groin incision. In the commoner properitoneal type, a groin incision should allow for an easy extraperitoneal removal of both the abdominal and scrotal portions of the sac. In some, the atrophied testis has been removed. The defect in the abdominal wall following excision of the hydrocele mass should be repaired by the approximation of the conjoined tendon to the inguinal ligament. Most operators leave a small drain in the scrotal cavity. In addition, a tight compression bandage over the

lower abdomen and scrotum appears to be very advantageous in avoiding a large accumulation of serous fluid in the operative wound.

### CASE REPORT

L. R., a 25-year-old man, was admitted to the hospital because of a swollen scrotum. Swelling in the right scrotal region, which had first been noticed 8 years previously, had increased more rapidly during the preceding 2 years and had occasionally been painful. On admission there was some abdominal swelling, but this caused no inconvenience.

The patient's general health was good. There were no serious illnesses or operations and no history of injury.

On physical examination, a visible mass causing deformity of the abdominal wall was evident in the right lower quadrant (Figs. 6 and 7). This mass, which was

FIGURE 6 *Lateral View of a Patient with an Abdominoscrotal Hydrocele.*

smooth and firm, extended from above the level of the umbilicus to the scrotum, and from the region of the left rectus muscle well into the right flank. The abdominal mass seemed to be contiguous with a right scrotal swelling

FIGURE 7. *Semilateral View of a Patient with an Abdominoscrotal Hydrocele.*

which had the typical consistence of fluid. The scrotal mass was easily transilluminated. Palpation of the scrotal mass caused a fluid wave in the abdominal portion. The swelling was not tender. There was a definite impulse on coughing. A tentative diagnosis of abdominoscrotal hydrocele was made.

On February 12, 1941, under spinal anesthesia, an oblique incision was made over the right lower quadrant and upper part of the scrotum (Fig. 8). The upper part of the incision included the fibers of the external oblique

FIGURE 8. Diagram of the Abdominoscrotal Hydrocele and the Incision Used for Removal.

muscle and the conjoined tendons, and the lower part the usual layers of the scrotal wall. A good line of cleavage was found at the level of the enlarged cystic mass. The mass was easily enucleated by blunt and sharp dissection

FIGURE 9. Photograph of the Excised Hydrocele Mass, Compared to a Large Lemon.

and was removed by being slid out through the incision, the scrotal part being first delivered. An atrophied spermatic cord was clamped and bisected. The operation was accomplished without opening of the sac or the peritoneal

cavity. The peritoneum was evident posterior to the hydrocele mass, but there was no evidence of any peritoneal reflection anterior to the mass. Fibers of the conjoined tendon and external oblique muscle were sutured to the inguinal ligament in an effort to support the lower abdominal wall. A small Penrose drain was left in the inguinal region, and one in the scrotal region. A firm

FIGURE 10. Hydrocele Sac Opened and Emptied, with a Small Testis at the Lower End.

compression bandage was applied to the lower abdominal and scrotal regions. Convalescence was uneventful.

The excised mass weighed 2600 gm. and contained 2000 cc. of olive colored fluid (Figs. 9 and 10).

#### SUMMARY

The literature on abdominoscrotal hydrocele is reviewed, and the condition is described. A report of a typical case, with a discussion of the operative technic employed, is presented.

## THE USE OF DILANTIN SODIUM IN BRONCHIAL ASTHMA: A PRELIMINARY REPORT

MAURICE H. SHULMAN, M.D.\*

SALEM, MASSACHUSETTS

THE modern therapeutic armamentarium for the treatment of bronchial asthma is not satisfactory. Skin testing, with subsequent attempts to remove all suspected allergens, has not proved completely successful. The recent literature<sup>1-5</sup> has shown the importance of understanding the "asthmatic personality" and the role of psychogenic factors in bronchial asthma. The psychologic forces operating in this disease become more apparent when one is faced with the failures that occur under the present accepted medical regime. The search for a method of treatment that would exert its effect through nervous avenues and would be generally applicable led to the use of Dilantin Sodium in cases of bronchial asthma.

Sodium diphenyl-hydantoinate, commercially known as Dilantin Sodium, was described in 1937 and 1938 by Merritt and Putnam<sup>6,7</sup> as a new anti-convulsant. The same authors<sup>8</sup> later reported excellent results with this drug in the treatment of epilepsy. Dilantin Sodium has, up to the present time, been applied solely in the treatment of epilepsy. The literature reporting its successful use in this condition has grown voluminous. Merritt and Putnam<sup>9</sup> report that "in addition to a

relief or a great reduction in the frequency of the attacks, it was frequently noted by the parents of children that they were much better behaved, more amenable to discipline, and did better work in school." This improvement, they contend, must have been due in great part to the freedom from attacks, but they believe that the medication may also have produced other changes in the activity of the cerebral cortex. They continue with the statement that further study may conceivably lead to the use of Dilantin Sodium in conditions with similar cortical dysrhythmias other than those in the convulsive state.

After extensive use of Dilantin Sodium in epilepsy, Merritt and Putnam<sup>9</sup> discussed in detail the toxic effects, the great majority of which occur only when large doses are employed. The gastrointestinal symptoms of Dilantin Sodium intoxication were chiefly nausea and vomiting. Symptoms of toxic action of the drug on the central nervous system consisted of nervousness, tremor of the hands, drowsiness and headache, and ataxia. In 5 per cent of the patients, a toxic dermatitis varying from an erythema to a severe morbilliform rash appeared. Hypertrophy of the gums occurred, particularly in children and young adults. Those

\*Member of Pediatric Clinic, Outpatient Department, Salem Hospital; associate pediatrician, North Shore Babies' Hospital.

patients taking 0.3 gm ( $4\frac{1}{2}$  gr) or less daily showed few or no toxic symptoms.

As discussed above, it was decided to employ Dilantin Sodium for the treatment of bronchial asthma in a selected series of cases. Only patients with repeated, frequent, acute attacks of asthma and a constantly "wheezy" respiration were included in the series. Every attempt was made to choose intractable cases of asthma that had not responded favorably to routine and accepted treatment. No case of purely seasonal asthma was included.

The ages of selected patients varied from three to fourteen years. The group included 4 boys and 3 girls, all of the white race. The sex factor was entirely coincidental.

All the patients tested in this experimental series had been skin tested. They were all found to be sensitive to many different foods as well as to many other irritants. Moreover, at different periods, all had had attacks of asthma severe enough to require subcutaneous adrenalin. Routine treatment of bronchial asthma had, in all these cases, been followed for varying lengths of time, with indifferent results. Such treatment had been given in each case for at least a year and in some cases much longer.

Dilantin Sodium was administered to the patients described below for periods varying from five months to one year. The first step before treatment was begun was the complete elimination of all other medication. Since the entire literature on Dilantin Sodium deals exclusively with its use in epilepsy, it was necessary to develop an arbitrary system of dosage for the treatment of bronchial asthma. The problem of controlling the administration of the drug in this series was solved by dispensing a week's supply to each patient at his or her weekly visit. This resulted in complete co-operation from the patients, as well as effective control of the doses taken. Each patient was first given 0.03 gm ( $\frac{1}{2}$  gr) morning and night. Results were evaluated on the freedom from attacks and the absence of wheezing. If, after observation of one week under this dosage, symptoms still persisted, the patient was then given 0.03 gm ( $\frac{1}{2}$  gr) three times a day. Dosage was increased by 0.03 gm ( $\frac{1}{2}$  gr) daily at intervals of one week until the patient reported no attacks of asthma and no wheezing on moderate exertion. By this method of self titration, it was found that 0.1 to 0.2 gm ( $\frac{1}{2}$  to 3 gr) daily was sufficient to keep the patients symptom free.

Each patient was advised to take part in all activities. No attempt was made to keep the children from entering situations and places that had

previously precipitated attacks of bronchial asthma. In fact, as treatment with Dilantin Sodium progressed successfully, they were deliberately encouraged to enter such exciting and irritating environs as fairs, moving pictures, fairs, circuses, parties and active games. Unrestricted diets were prescribed. Living quarters were not changed and sleeping chambers were not specially prepared for the elimination of dust.

### CASE REPORTS

**CASE 1** E. K., a 5 year old girl, only child with no family history of allergy in infancy had severe eczema, which began to clear when she was about 2 years old. She was first seen at the age of 3 because of a persistent cough and wheeze following tonsillectomy. On examination a diagnosis of bronchial asthma was made. Subsequent attacks of asthma occurred at about weekly intervals. Routine skin testing showed positive reactions to many foods. No positive reactions were obtained when scratch tests were done with epidermids, grasses and weeds. The patient continued to have frequent attacks after the elimination of all known irritating factors; the medication consisted of ephedrine sulfate and allied drugs which gave partial relief. Over a period extending from April 1939, to July 1940, she had twenty four attacks of asthma severe enough to require injections of adrenalin in oil. All exciting play and activity had to be restricted because they apparently precipitated attacks. In July, 1940 the patient was first given Dilantin Sodium. After a few weeks of trial the dosage was established as 0.1 gm ( $\frac{1}{2}$  gr) morning and night. No severe asthmatic attacks have occurred since that time, and she leads an active, normal life. There has been occasional wheezing respiration, but this occurs so infrequently and is so mild that no other medication is required and her normal activities are not interrupted. There has been no change in her environment since she was first seen. She resides in the same house, and her sleeping quarters are the same. She observes no dietary restrictions. Her general physical condition is good, and her appetite unimpaired.

**CASE 2** P. M., a 14 year old girl, had a pronounced family history of asthma. Her father and her two brothers had bronchial asthma. The patient had eczema in infancy, which cleared. She was first seen in January, 1941, with an acute asthmatic attack. She had been having severe attacks about once each week for the previous 8 years. These attacks lasted 24 to 48 hours. For relief she had been taking ephedrine capsules as well as inhaling some powder that her father used. Incomplete skin testing showed a marked allergy to many foods and a strong reaction to ragweed and goldenrod. The patient appeared poorly nourished and was found to be 14 pounds under weight. She was listless and disinterested in all activities. Her schoolwork was poor. Dilantin Sodium—0.03 gm ( $\frac{1}{2}$  gr) morning and night—was ordered. With this dosage of the drug she had many mild attacks. The dosage was slowly increased to 0.1 gm ( $\frac{1}{2}$  gr) morning and night. The symptoms then disappeared. The patient had been able to take active part in winter sports and to skate, run and go out in cold and snowy weather—these activities had previously precipitated attacks. She has had several upper respiratory infections but no subsequent asthma or wheezing. Her schoolwork has improved, and her parents describe her general mental attitude as much brighter. There has been no restriction in diet.

and no change in environment. Her appetite is excellent, and she has gained 8 pounds in weight.

CASE 3. M. M., a 9-year-old boy, was seen because of frequent "colds and cough" for the previous 5 years. At the age of 6, he had a tonsillectomy, with no relief. For the past 2 years, he had had attacks of bronchial asthma at intervals of about 2 weeks. No family history of allergy could be obtained. When first seen in December, 1940, the patient was having a severe asthmatic attack and had difficulty in walking up a few steps. His chest was fixed, and his breathing noisy and labored. Complete skin testing revealed sensitivity to many foods, as well as to dust, chicken feathers and ragweed. He was given Dilantin Sodium in doses of 0.03 gm. ( $\frac{1}{2}$  gr.) morning and night. Wheezing continued until the dosage was increased to 0.03 gm. ( $\frac{1}{2}$  gr.) thrice a day. With this dosage, all symptoms disappeared until March, 1941, when the patient had a severe upper respiratory infection, with some wheezing. Prompt relief was obtained by increasing the dose of Dilantin Sodium to 0.06 gm. (1 gr.) morning and night. There have been no attacks and no wheezing since that time. His general physical condition has improved, and he has gained about 7 pounds. He is now able to take part in all active sports, and his family reports a marked lessening of irritability. His school grades and attendance record for this year are excellent as compared with those of the previous year. There has been no opportunity to observe the effect of Dilantin Sodium on his seasonal allergy.

CASE 4. G. A., a 10-year-old boy with no family history of allergy, had two attacks of lobar pneumonia in 1935, at 4 years of age. On recovery, he began to have attacks of bronchial asthma. He was first seen in 1937, when he was 6 years old, and was referred to a Boston hospital for treatment. Skin tests at that time revealed sensitivity to many foods, as well as to ragweed and grasses. Since then, the patient had received various kinds of treatment, including osteopathic manipulation. Attacks occurred at about weekly intervals, but the patient was never completely free of symptoms. Because of his constant asthma, his activities were so restricted that he was practically an invalid. In December, 1940, he was given 0.03 gm. ( $\frac{1}{2}$  gr.) Dilantin Sodium morning and night. It was necessary to increase the dosage rapidly to 0.1 gm. ( $\frac{1}{2}$  gr.) morning and night. Since the establishment of this dosage, the patient has had no attacks of bronchial asthma until the onset of his seasonal allergy. He has been able to take an active part in sports, and his schoolwork has shown marked improvement. He eats well and sleeps well. At present, he shows a gain of 8 pounds in weight. He is an entirely new personality, sparkling and lively. There has been no change in environment, and his diet is entirely unrestricted.

Since May, with the onset of this year's seasonal sensitivity to the grasses, he has had some wheezing and labored breathing, but no severe asthmatic attacks. Increasing the dose of Dilantin Sodium to 0.1 gm. ( $\frac{1}{2}$  gr.) thrice a day has had no appreciable effect. His present symptoms, however, are relatively mild and do not restrict his activities.

CASE 5. M. N., a six-year-old boy, had been seen at intervals since birth. Both his mother and father were allergic. From infancy, he had frequent attacks of spasmodic bronchitis, but otherwise his early history was essentially unremarkable. He had always been a high-strung, nervous boy—always a problem to control. He was pampered and markedly overprotected. In 1937, the patient had a severe case of pertussis. Convalescence was prolonged. Six

months after recovery, he developed pneumonia. Recovery was again prolonged and was immediately followed by attacks of severe bronchial asthma. These attacks occurred at about weekly intervals. The patient was seen by an allergist, and skin tests showed a mild sensitivity to some foods. No grasses or weeds gave positive results. Even with elimination diets and complicated attempts to avoid contact with suspected irritating allergens, combined with the administrations of ephedrine sulfate and other standard treatment, he had little if any relief. Any new or exciting situation seemed to precipitate an attack. He was much restricted in his play by the parents and was absent from school a great deal.

In March, 1941, treatment with Dilantin Sodium was begun, following a severe asthmatic attack. The boy was first given 0.03 gm. ( $\frac{1}{2}$  gr.) morning and night; this was found to be insufficient. In about 2 weeks, the dosage was increased to 0.03 gm. ( $\frac{1}{2}$  gr.) in the morning and 0.1 gm. ( $\frac{1}{2}$  gr.) at night. He began to take part in social and physical activities, and his attendance record at school was excellent. Three upper respiratory infections with hyperpyrexia occurred, but did not, in contradistinction to the past record, result in attacks of bronchial asthma.

At the end of 2 months of treatment, the patient developed what his mother called an asthmatic attack. During this attack, his breathing was labored and he wheezed, but no rales could be heard in the chest. All these symptoms were pronounced when the patient was being examined or discussed, but disappeared when his attention was occupied. He has had four or five such episodes since, none of which required special treatment. It was believed that these attacks were not true asthmatic attacks, but there is much evidence that they were used as a device to attract attention. Because of the parents' extreme anxiety about the boy, however, he was referred to an allergist and an otolaryngologist for further checkup.

CASE 6. P. B. F., a 4-year-old boy with a family history of allergy—his paternal uncles and his father had severe hay fever—had an obstinate infantile eczema. At about 3 years of age, he developed frequent attacks of bronchial asthma. Skin tests showed marked positive reactions to many foods, as well as to the grasses and weeds. Asthmatic attacks occurred throughout the entire year at about weekly intervals. A tonsillectomy was done in November, 1940. Convalescence was uneventful, and the patient had no asthmatic attacks until March, 1941. With the resumption of attacks of bronchial asthma at that time, Dilantin Sodium treatment was begun. The initial dose was 0.03 gm. ( $\frac{1}{2}$  gr.) morning and night. Some symptoms persisted until the patient was taking 0.1 gm. ( $\frac{1}{2}$  gr.) morning and night. At this dosage level, he was symptom free. Marked improvement was also noted in the residual eczema.

With the onset of his seasonal allergy,—caused by the grasses,—the patient's mother reported that he had moderate attacks of sneezing, morning and night. In an attempt to overcome these symptoms of vasomotor rhinitis, the dose of Dilantin Sodium was increased to 0.2 gm. (3 gr.) morning and night. This increase had little effect on the spasms of sneezing. One week after the patient began to take the 0.4 gm. (6 gr.) daily, he developed signs of central-nervous-system intoxication. He complained of dizziness, diplopia, nausea and vomiting, and a staggering gait was noticed. The drug was then discontinued for 5 days, during which he had several attacks of bronchial asthma. Dilantin Sodium was resumed in doses of 0.03 gm. ( $\frac{1}{2}$  gr.) morning and night. Complete

relief from asthmatic symptoms was not obtained until he was given 0.1 gm (1½ gr) morning and night. His spasms of sneezing persisted.

This child was always markedly overprotected and his activities greatly limited. His mother reported that he was always hyperactive, irritable and in some respects social. With the improvement in his asthmatic symptoms since taking Dilantin Sodium, he has been allowed more freedom of action and diet. At present he is much more pleasant and amenable.

**CASE 7.** D. R., a 3-year-old girl with no family history of allergy, had eczema which had persisted since early infancy. In November, 1940, this patient—an only child—was seen with an attack of bronchial asthma. Her mother denied any previous attacks. These attacks occurred at frequent intervals. Skin tests revealed sensitivity to many foods, but no reaction to the grasses and weeds. In January, 1941, the patient was started on 0.03 gm (½ gr) Dilantin Sodium morning and night. At weekly intervals the dose was increased to 0.1 gm (1½ gr) morning and night. At this level, the patient remained free of any asthmatic attacks for months. The eczema also improved markedly.

In May, the child's mother failed to return for her supply of Dilantin Sodium, and the patient remained without treatment for a week. At the end of that time, she was again seen with a moderately severe attack of bronchial asthma. Dilantin Sodium, 0.1 gm (1½ gr) morning and night was again given with complete cessation of symptoms. With this dosage, the patient has remained symptom free.

#### SUMMARY

Because of recent work on the psychogenic aspect of bronchial asthma and the concept of the so-called 'asthmatic personality,' a search was made for a drug that would have a psychosomatic effect on children with bronchial asthma. Recent work with Dilantin Sodium and its application in the treatment of epilepsy have amply proved this to be a powerful and efficient anticonvulsant. The infrequency of toxic effects, in addition to its reported effect of improvement in the epileptic personality, marked the drug as one worthy of trial in cases of bronchial asthma.

Seven cases of intractable, severe bronchial asthma were selected for treatment with Dilantin Sodium. These cases were skin tested and were found to be sensitive to many different allergens. The ages of the patients ranged from three to fourteen years. The sex factor was not controlled although in this series there were 4 boys and 3 girls. The patients received Dilantin Sodium for periods varying from five months to one year, although several were studied for a far greater length of time.

The dosage of Dilantin Sodium was determined for each patient by "self titration" methods. When adequate dosage was maintained, 6 patients remained consistently free from attacks of bronchial asthma. Two patients reported abortive at-

tacks, consisting of slight wheezing, which passed off rapidly. In only 1 case did toxic symptoms result from the ingestion of the drug. In this case, the toxic symptoms cleared rapidly on withdrawal of the drug, and the patient was able to resume treatment with a slightly smaller dose.

In 2 cases complicated by seasonal allergies, nasal and ocular symptoms of the allergy occurred and could not be controlled with Dilantin Sodium.

During the administration of the drug, there were no change in environment and no dietary restriction. During this period, some of the patients suffered acute upper respiratory infections, with no resulting bronchial asthma in sharp contrast with the previous history of these patients. To test the efficacy of Dilantin Sodium in controlling asthmatic attacks brought on by emotional upsets, many patients were encouraged to enter situations and environments that formerly precipitated attacks of bronchial asthma. With this drug as the sole medication, the patients were consistently free of attacks of bronchial asthma, and they were able to engage normally in athletic and social activities. In the 1 case in this series in which complete success was not obtained the lack of parental co-operation and understanding was an important factor.

Cases 2, 3 and 4 were marked by a distinct change in personality with lessening of irritability. The patients were reported to be much brighter mentally and much easier to live with. In Case 2 a distinct improvement in schoolwork was noted.

In 2 cases a stubborn eczema which had persisted since infancy cleared to a remarkable degree while the patients were taking Dilantin Sodium.

#### CONCLUSIONS

Dilantin Sodium gave marked relief in 6 of 7 cases of bronchial asthma.

The drug must be given continuously to prevent the attacks.

The modus operandi of this drug in cases of bronchial asthma cannot be determined from the results with this small group of patients.

Personality changes were observed in these patients.

Concomitant eczema improved with the administration of Dilantin Sodium in 2 cases.

A new field of investigation which requires much more clinical and laboratory work with Dilantin Sodium in bronchial asthma is open.

## CLINICAL NOTE

### THE ASSOCIATION OF PRIMARY NEOPLASM OF THE LIVER WITH HEMOCHROMATOSIS\*

REPORT OF A CASE

ERNEST W. SAWARD, M.D.†

BOSTON

IT IS widely recognized that the severer grades of diffuse hepatic cirrhosis are frequently complicated by a primary hepatic neoplasm. Counselor and McIndoe<sup>1</sup> reported 5 such cases in 127 cases of portal cirrhosis, an incidence of 3.9 per cent. Stewart<sup>2</sup> collected 9 cases in 120 cases of well-marked cirrhosis, an incidence of 7.3 per cent. The first authors even suggest that primary carcinoma of the liver develops in 3 to 4 per cent of patients with cirrhosis.

This type of neoplasm also occurs in association with another type of cirrhosis, namely hemochromatosis. In this disease, the fibrosis is believed to result from the reaction to a diffuse deposit of hemosiderin throughout the liver and other organs. Sheldon,<sup>3</sup> in his excellent monograph on hemochromatosis, published in 1935, collected from the literature 345 cases in which 20 patients had primary cancer of the liver, an incidence of 5.8 per cent. This is in agreement with the figures for cirrhosis in general.

The following case of hemochromatosis is reported as an example of this interesting association with hepatoma.

#### CASE REPORT

G. M. (P. B. B. H. Medical 59247), a 62-year-old married man, entered the medical service of the hospital on March 16, 1941, with the complaint of weakness. For several years, he had noticed gradually increasing pigmentation of his skin, without other symptoms. Three months before entry, he noticed a rather sudden onset of weakness, anorexia, polydipsia and polyuria, and was found to have glycosuria by his local physician. He was regulated satisfactorily by dietary management with 22 units of protamine insulin and 30 units of regular insulin every morning. Two weeks prior to entry, the patient noticed marked

weakness in his left arm and leg and soon became unable to raise his left hand.

The family history was noncontributory. He had enjoyed excellent health until his present illness. He did not use alcohol, and he had not been exposed to any occupational hazard.

Examination showed a well-developed, moderately obese and chronically ill elderly man. The skin was generally pigmented brown, most markedly on the forearms and

FIGURE 1. Photograph of a Section of the Liver, Showing Fibrosis and the Deposition of Hemosiderin.

abdomen. There was slight pigmentation of the oral mucous membranes and at the angles of the lips. Body and axillary hair was scant, and the pubic hair was of the female configuration. The blood pressure was 96/50; 6 weeks previously, it had been 140/70. The heart was not enlarged, the rate and rhythm were normal, the sounds were distant, and no murmurs were heard. The lungs were clear. The liver edge was felt 4 cm. below the right costal margin and was smooth and firm. There was no free fluid in the abdomen. The cranial nerves were intact, but there was marked weakness of the left arm and leg. Sensation was unimpaired. The tendon reflexes were slightly diminished on the left side. There was no Babinski sign on either side.

The blood Hinton reaction was negative. Examination of the blood showed a red-cell count of 4,590,000 with a hemoglobin of 100 per cent (Sahli), and a white-cell count of 10,000. Urine analysis showed a +++ test for sugar, but no acetone. Blood chemical findings were a nonprotein nitrogen of 27 mg., a sugar of 218 mg., a cholesterol of 170 mg. and a serum protein of 7.5 gm. per 100 cc., with an albumin of 3.7 gm. and a globulin of 3.8 gm. per 100 cc. The carbon dioxide combining power was 20 milliequiv. per liter, the sodium 127 milliequiv. per liter, the icteric index 17, and the sedimentation rate 5 mm. per hour. A bromsulphalein liver-function test showed 90 per cent retention in 30 minutes. The vital

†Formerly, assistant resident physician, Peter Bent Brigham Hospital.

capacity was 1700 cc. The basal metabolic rate was -2 per cent. An electrocardiogram showed low voltage, premature auricular beats and a very small R wave in Lead 4F.

The clinical course was afebrile except on one occasion, when there was a rise in temperature to 101°F. Because of the symptoms of weakness and nausea and the findings

FIGURE 2 Photograph of a Section of the Hepatoma

of low blood pressure, pigmentation of the oral mucous membranes and low blood sodium, the possibility of a concurrent adrenal insufficiency was considered. Accord-

FIGURE 3 Photograph of a Section of a Metastasis in the Adrenal Gland

ingly sodium chloride was added to the diet, and 70 mg per day of desoxycorticosterone acetate was administered intramuscularly. The patient became weaker, and neither the blood pressure nor the blood sodium rose. Despite 50 units of regular insulin daily, the blood sugar rose to 450 mg per 100 cc. Cheyne-Stokes respirations became apparent, and the venous pressure increased to the equivalent of 240 mm of water. The patient was rapidly digitalized. On the 6th hospital day, acute pulmonary edema developed, and the patient expired while a phlebectomy was being attempted.

**Autopsy.** The principal findings at autopsy consisted in hemochromatosis, with marked atrophy and fibrosis of the pancreas, cirrhosis of the liver and malignant hepa-

toma (Fig 1). The last had metastasized to the lymph nodes at the hepatic hilus and to the right cerebral hemisphere (Fig 2). No lung metastases were seen. Pigment deposits consisting predominantly of hemosiderin and to a lesser extent of hemofuscin were present in all organs. They were most abundant in the pancreas, liver and lymph nodes. The heart and particularly the parathyroid, thyroid and pituitary glands, epididymis and choroid plexus represented other sites of marked pigmentation. The adrenal glands displayed a fair degree of pigmentation (Fig 3) but were not otherwise histologically unusual. The heart weighed 380 gm, the liver 2560 gm, and the pancreas 160 gm. The tumor in the liver measured 4 by 5 by 7 cm, and the metastatic nodule in the brain was 11 cm in diameter (Fig 4).

Inasmuch as the presence of the hepatoma was unsuspected clinically in this case, the discovery that the cerebral metastases accounted for the hemiplegic symptoms was doubly surprising. Involvement of the brain by metastasis from a liver-

FIGURE 4 Photograph of a Section of a Metastasis in the Brain

cell carcinoma is unusual. Of 33 cases of hepatoma with ordinary cirrhosis and 17 with hemochromatosis reported by Stewart,<sup>2</sup> none had secondary involvement of the brain by the tumor.

Adrenal insufficiency was suggested clinically by asthenia, nausea, low blood pressure, low blood sodium and pigmentation of the oral mucous membranes, in addition to the pigmentation of the skin. Lack of response to salt and desoxycorticosterone therapy, however, as well as the only slightly altered histologic appearance of the adrenal glands at autopsy, made this uncertain. The role of other endocrine gland changes in the production of symptoms in this disease has led to speculation. Butt and Wilder<sup>4</sup> suggest that impotence and atrophy of the hair and skin may be due to a deposition of hemosiderin in the anterior lobe of the hypophysis. To explain the pigmenta-

tion of the oral mucous membranes, these authors suggest a deposit of melanin secondary to the involvement of the adrenal gland by hemosiderin. These hormonal interrelations are of interest but are difficult to analyze.

### SUMMARY

A case of hemochromatosis is reported in which a primary hepatoma with metastasis to the brain occurred. The relation of hepatoma to hemochromatosis is discussed. Some of the clinical features

of this case could be attributed to adrenal insufficiency.

I am indebted to Dr. Orville T. Bailey for the photographs used in this report.

## MEDICAL PROGRESS

### TOXIC REACTIONS FOLLOWING SULFONAMIDE TREATMENT\*

CHESTER S. KEEFER, M.D.†

BOSTON

THAT toxic reactions follow the use of the various sulfonamides is well known. That they vary in their frequency and severity, as well as in their clinical features, is also well recognized. The purpose of this report is to summarize the various toxic reactions as they are observed in patients following sulfonamide treatment, and to discuss their significance.

For purposes of discussion, the toxic reactions can be divided into several groups in accordance with the system involved and the time of their occurrence (Fig. 1). Toxic reactions referable to the gastrointestinal tract, the hematopoietic and the renal systems are the most important and frequent. The time of their occurrence may be divided into the prompt, the accelerated and the delayed reactions. Although there is very little information available concerning the precise mechanism of the production of side effects, it seems clear that some of the reactions are due to the direct toxic effect of the drugs on tissues, whereas others are due to hypersensitive reactions that are similar in many respects to drug hypersensitivity in general.

### SKIN REACTIONS

Among the common untoward reactions to the sulfonamides are various skin eruptions. They are

characterized by their pleomorphism, and are frequently accompanied by other signs of drug intoxication or hypersensitivity. They vary in frequency with different drugs (Table 1), and they are often widespread in distribution. The lesions cannot be inhibited by the administration of para-aminobenzoic acid. There is nothing distinctive about the eruptions, since they may be erythematous, morbilliform, urticarial or purpuric, and in some cases a generalized exfoliative dermatitis, with massive edema, appears. Lesions resembling erythema nodosum are most frequently seen following sulfathiazole therapy. One of the curious features of some of the cases of dermatitis, especially those following sulfanilamide, is the fact that the eruption develops after exposure to sunlight or, at least, is made worse following such exposure.

The skin eruptions occur at one of three periods following the administration of the drugs. The usual time is between seven and nine days after the drug is started, although the lesions may appear as early as the fourth day or as late as the fourteenth day (delayed reaction). They may occur, however, as a prompt or accelerated reaction within twenty-four hours after the drug has been started, or as late as two to six weeks. When the skin eruptions are prompt or accelerated, they almost invariably occur in persons who have previously received the same or a closely related drug. For example, the usual story is that they received the same or a different sulfonamide at some time in the past, and that a reaction consequently followed within seven to fourteen days. This delayed reaction, which was self-limited in duration, disappeared following withdrawal of the drug. Then,

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

after an interval varying from a few days to months or even several years, the same drug or a different one is given, with a prompt reaction. The prompt reactions may occur after single small

who have previously had the drug without any noticeable reactions. Patients who have acquired sensitivity to sulfapyridine may react in a similar manner to sulfamethylthiazole or sulfapyridine

doses, and they may be more extensive and serious than the previous reactions, since they are sometimes associated with exfoliative dermatitis or

but not to sulfanilamide, and patients who are sensitive to the esters of para-aminobenzoic acid (procaine hydrochloride) may be sensitive to sul-

TABLE 1. Frequency of Toxic Reactions Following Various Sulfonamides.

TOXIC REACTION	SULFANILAMIDE	SULFAPYRIDINE	SULFATHIAZOLE	SULFAGUANIDINE	SULFADIAZINE

the signs of toxic hepatitis. Although these prompt or accelerated reactions occur oftenest in patients who have had reactions following the first experience with the drug, they may appear in those

fanilamide (para-aminobenzoic sulfonamide). It is plain, then, that the hypersensitivity to the drug may be specific, and that the reactions may follow the exhibition of a closely related drug. This

suggests that there is a common substance in the various drugs to which some patients become sensitive.

In most cases, the prompt hypersensitive skin eruptions are accompanied by fever, and in some, they may be associated with such features as toxic hepatitis.

Delayed skin eruptions, which were first described by Hageman and Blake, occur commonly between the seventh and the ninth day after the drug is started, and fever is associated with the eruption in about half the cases. The fever may subside within two to seven days after the drug is withdrawn, but the skin eruptions may persist for several weeks or even longer. Other associated features are generalized edema, enlargement of the lymph nodes, leukocytosis (often reaching a count of 70,000 or 80,000), transient jaundice without anemia, and eosinophilia (20 to 55 per cent). The delayed skin eruptions may also be a feature in the patients with neutropenia or in the cases of jaundice occurring as late as the sixth week after the drug has been discontinued.

#### FEVER

Febrile reactions following the sulfonamides may be prompt, accelerated or delayed. They may occur alone, with a skin eruption, or with other manifestations of drug intoxication or hypersensitivity. They may be superimposed on the fever of infection, or they may appear after the fever of infection has disappeared. In a few cases, they occur several days after the drug has been discontinued. These episodes are usually self-limited and last from two to nine days, the usual duration being two to four days. They occur with varying frequency following the different sulfonamides and are commonest after sulfathiazole and least common following sulfadiazine (Table 1).

Patients who develop febrile reactions within the first twenty-four hours have almost invariably received the drug previously, with or without signs of intoxication. When the fever develops or is increased within two to six days following its exhibition, there is generally an associated hemolytic anemia.

Prompt febrile reactions following a single dose of the sulfonamides may be an isolated feature, or they may be followed or accompanied by a skin eruption, toxic hepatitis, leukopenia or hemolytic jaundice.

The onset of the fever may be very abrupt and accompanied by a chill and a skin eruption. Such reactions usually follow the repeated use of the same or a related drug, although a patient may be

sensitive to one and not to another. Dowling has reported that a patient who reacted to a second dose of sulfadiazine failed to react to sulfathiazole, sulfapyridine or sulfanilamide. Davidson and Bullowa reported a case in which fever and a skin eruption followed the use of sulfapyridine or sulfamethylthiazole in a patient with acquired sensitivity to sulfapyridine; the same patient, however, failed to react to sulfanilamide.

#### RENAL COMPLICATIONS

Three renal complications may follow the use of the sulfonamides: hematuria, renal colic, and oliguria or anuria. They have been described following sulfapyridine, sulfathiazole and sulfadiazine, but not after sulfanilamide (Table 1). To understand these phenomena, one must be familiar with the facts concerning the excretion of the free and combined or acetylated sulfonamides by the kidney. It is now firmly established that, once the various sulfonamides are absorbed from the gastrointestinal tract, a part of the drug remains free and the remainder is changed by the process of acetylation to the combined form, and both fractions are excreted almost quantitatively by the kidney. The acetylated drugs are more insoluble than the nonacetylated, so that when the urine is concentrated by reabsorption of water by the kidney tubules the precipitation of the acetylated compounds is likelier to occur than that of the free compounds. The crystals may form in the tubules or the pelvis of the kidney, or they may precipitate out in the ureters or the bladder; in either event, they cause obstruction to the free flow of urine, and oliguria or anuria may follow. This may be preceded by attacks of renal colic or hematuria, or both. The hematuria is not always associated with renal colic, and may occur without any of the signs of obstruction. In these cases, it is difficult to escape the conclusion that there has been actual irritation of the glomeruli. When there is oliguria or anuria, the nonprotein nitrogen of the blood increases, and signs of renal insufficiency and even uremia may follow. It is rare indeed for any patient who has shown symptoms and signs of renal insufficiency during sulfonamide therapy to continue to show them following the discontinuation of treatment, unless the kidneys have been insufficient prior to the drug treatment. In other words, if permanent renal damage ever occurs from sulfonamide treatment, it must be exceedingly rare.

From what has been said, it is apparent that the concentration of the urine, the duration of treatment and the functional capacity of the kidney prior to administration of the drug are all impor-

tant considerations in the renal complications of sulfonamide therapy.

Hematuria, which is the commonest manifestation of renal irritation, may occur as an isolated feature or in association with renal colic. It is more frequently seen after sulfapyridine than after sulfathiazole or sulfadiazine, probably owing to the variation in the amount of drug acetylated before it is excreted by the kidney. Hematuria may occur as early as the first day of treatment in patients receiving intravenous therapy, but, as a rule, it is seen on the second and third days, or later. In several reported cases, renal colic and hematuria appeared several days after the drug had been discontinued, probably because the fluid excretion was decreased before all the drug had been eliminated from the body. Generally speaking, hematuria disappears following discontinuation of the drug and the forcing of fluids to 2500 cc daily.

When the fluid intake is inadequate because of vomiting, stupor or the intoxication accompanying the infection, or when renal insufficiency precedes the use of the drugs, oliguria and even anuria may occur. When the sodium salts are given intravenously, hematuria and oliguria may be seen within twenty-four to forty-eight hours. In most cases, however, oliguria is first noticeable after the drug has been given for several days. It is for this reason that the fluid intake and urinary output should be watched carefully so long as the drug is being given. Nitrogen retention accompanies the oliguria, and in many cases, the symptoms and signs of uremia develop. If any of these signs appear, the drug should be discontinued at once, the fluid intake increased to at least 3000 cc a day, and cystoscopy carried out to ascertain whether there is an obstruction of the ureters. Aside from agranulocytosis, the renal complications are the most serious and require prompt action if they occur during the course of the treatment.

#### JAUNDICE

Following the use of the sulfonamides, particularly sulfanilamide, jaundice is occasionally encountered, owing to the development of a hemolytic anemia or a toxic hepatitis. Associated with the jaundice, there may be an exfoliative dermatitis, other skin eruptions or neutropenia. The time of the appearance of the jaundice is significant. It may be accelerated or delayed. During the first week of treatment, icterus usually signifies a hemolytic anemia.

When delayed, the jaundice may appear between the eighth and the fourteenth day, or even later. It is accompanied in most cases by exfoliative

dermatitis—occasionally, by neutropenia. One case has been reported by Garvin in which jaundice and exfoliative dermatitis were observed six weeks after the drug had been discontinued.

In the cases associated with the signs of hemolytic anemia, the jaundice is due to increased blood destruction as well as to toxic hepatitis, since bilirubin appears in the urine and the bromsulfalein test usually shows retention of dye. Watson and Spink have demonstrated impaired liver function following the administration of sulfanilamide.

When jaundice without anemia occurs within a few days after the drug is started, this usually means that the patient has been sensitized to the drug by a previous experience with it. As a rule, there was some sign of intoxication during the first course of treatment, but the signs of intoxication may have been absent. It is well to remember, as previously mentioned, that sensitization may occur without causing symptoms or signs at the time, the only evidence of sensitization appearing after the second exhibition of the drug at a later date. Cases have been observed in which jaundice followed a small amount of the drug, and was preceded by a chill, high fever and a skin eruption. Patients who have previously shown signs of hypersensitivity should never be given the drug a second time.

Enlargement of the liver and spleen and, in occasional cases, ascites accompany the jaundice. In most of the reported cases of toxic hepatitis, the prognosis is favorable, although it is poor when exfoliative dermatitis or neutropenia is also present.

#### ANEMIA

Anemia following the sulfonamides is of two types: acute hemolytic and slowly progressive. It is most frequent after sulfanilamide, but it may occur after any of the drugs (Table I). Harvey and Janeway were the first to report acute hemolytic anemia following sulfanilamide, and since then it has been observed with varying frequency in different clinics. Wood states that 24 per cent of adults and 8.3 per cent of children developed acute hemolytic anemia following sulfanilamide. This is the highest recorded incidence of this complication, but it serves to stress its importance.

Briefly, the course of the acute hemolytic anemia is as follows. Within one to seven days after sulfanilamide is started, the patient begins to complain of nausea and dizziness. There is commonly an exacerbation or an onset of fever. Within a short time, the patient becomes pale and sometimes icteric because of the rapid destruction of blood. The blood shows an anemia, with leuko-

cytosis; there are urobilinogenuria, bilirubinemia and, in some cases, hemoglobinemia and hemoglobinuria. Following the discontinuance of the drug, the forcing of fluids, and blood transfusions, recovery occurs in most cases, although the anemia may persist for as long as two to four weeks.

The leukocytosis may be very high with a leukemoid reaction; that is, the white-cell count may be well above 100,000, and nucleated red blood cells and myelocytes may be present in increased numbers.

From the studies of Watson and Spink, as well as those of Ham and of Antopol, Goldman and Sampson, it is now evident that profound changes occur in the hemoglobin metabolism and in the red blood cells of patients receiving sulfanilamide. Evidence of increased blood destruction and changes in the fragility to varying concentrations of salt solutions has been obtained, and suggests that sulfanilamide in some mysterious way makes the red blood cells vulnerable to rapid destruction. At the same time, it has a profound effect in the bone marrow, causing the changes that are responsible for the hyperleukocytosis with leukemoid reaction.

Of great significance is the observation that a recurrence of the anemia may follow the second course of the drug.

The second type of anemia, namely, the slowly progressive form, is exceedingly common in patients who receive large amounts of the sulfonamides for two weeks or longer. This type is difficult to interpret, since the infections that are being treated are often contributory. There seems to be no doubt that the anemia in many of these cases is due to the sulfonamides, since it occurs in patients with infections, such as gonococcal arthritis, that in themselves do not produce anemia. Some of these patients show splenomegaly. In any case, therefore, it is well to remember that a slowly progressive anemia is common following sulfonamide treatment, and that adequate means should be taken to recognize and treat it.

#### NEUTROPENIA AND AGRANULOCYTOSIS

A decrease in the total leukocyte count below 5000, with or without a corresponding decrease in the granulocytic cells, is not too uncommon following sulfonamide treatment. It is most frequently observed following sulfanilamide, and less often following sulfapyridine and sulfathiazole (Table 1). Although leukopenia is not infrequent after sulfadiazine, agranulocytosis must be rare, since, so far as I can determine, it has not been reported.

When agranulocytosis appears, it is a most serious complication: about 70 per cent of patients die. The usual time of its occurrence is between the fourteenth and the twenty-first day after the drug has been started, and it is most frequent in patients who have received a large amount of the drug continuously for that length of time. Occasionally, agranulocytosis is observed as early as the sixth or as late as the thirty-fifth day. In a few cases, it appears within a few days to two weeks after the drug has been discontinued. Once leukopenia occurs and the patient recovers, neutropenia and fever frequently develop following the second attempt to resume treatment. This was a feature of the case described by Jones and Miller.

The onset of agranulocytosis is usually accompanied by fever, sore throat, ulcerative stomatitis and pharyngitis, and a skin eruption. In a few patients, jaundice develops. Other signs of drug intoxication often precede the onset of agranulocytosis, such as skin eruptions, fever, anemia, jaundice and leukopenia. When these features appear, treatment should immediately cease.

The course of agranulocytosis is usually rapidly fatal in at least 70 per cent of all cases, and death occurs between four and six days following the onset of symptoms. The treatment consists in stopping the drug, the use of Pentnucleotide and blood transfusions, and the local treatment of the throat infection. This subject has been adequately reviewed in a recent progress report by Jackson.

#### MISCELLANEOUS AND INFREQUENT SIGNS OF INTOXICATION

##### *Ocular Lesions*

The following affections of the eyes have been observed: conjunctivitis and scleritis, acute myopia, optic neuritis and yellow vision. Conjunctivitis and scleritis are encountered following sulfathiazole. Acute myopia has followed sulfapyridine, with edema of the lens. Temporary optic neuritis has been described after sulfanilamide, and yellow vision was complained of by one of Dowling's patients following sulfadiazine. All these disturbances are temporary and subside when the drug is withdrawn.

##### *Symptoms Referable to the Central Nervous System*

*Psychoses.* Irritability, drowsiness and stupor, with mental depression, disorientation as to time and place, and hallucinations, are not infrequently encountered during treatment with the sulfonamides, and disappear rapidly once the drug is discontinued. The relative effect of the infection itself

and of the drug in causing the mental symptoms is sometimes difficult to assess, since many patients with pneumonia or other febrile illnesses ordinarily develop delirium or other signs of mental disturbance during their infections. There is no doubt, however, that the sulfonamides contribute to the production of temporary mental disturbances in some cases, since their withdrawal is followed by the disappearance of these symptoms.

**Polyneuritis.** A rare complication of sulfonamide treatment is polyneuritis, especially after sulfanilamide or sulfathiazole. In most of the reported cases, the drug was given in large amounts over a period of several weeks. The prognosis is usually good, although at least several months may be required for the patient to recover.

**Thrombopenic Purpura Hemorrhagica**

This is a rare complication of sulfanilamide or sulfapyridine intoxication, and one that should call for immediate discontinuation of the drug. On the whole, the prognosis is good following withdrawal of the drug.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 28071

#### PRESENTATION OF CASE

A forty-five-year-old housewife was admitted to the hospital because of profuse vaginal bleeding of eight hours' duration, following a long course of menstrual irregularity.

Following the menarche, at twelve years, the menses were quite profuse. At the age of twenty-one, the patient received three radium treatments in another hospital, following which the menses stopped for six weeks. At the age of about thirty, a "tube and ovary" were removed at the other hospital, and another course of radium therapy was given. In the seven years following this, the menses were absent, and the patient experienced hot flashes. The menses then returned, and were regular, although scanty. Following the last regular period, one year before entry, there was amenorrhea lasting seven months. There was then slight, continuous bleeding for two months, stopping two days before entry. Following a strenuous evening, the patient was aroused early in the morning by profuse vaginal bleeding, with the passage of large clots. Throughout the course of the illness, there were no other symptoms until the last episode of vigorous bleeding, when there was some cramping. The patient had been married for seven years but had never been pregnant.

The family history was irrelevant. Appendectomy and cholecystectomy had been performed some years previously.

On admission, the patient appeared well developed and nourished. The chest and upper abdomen were normal. There was moderate suprapubic tenderness, with slight resistance to palpation. There was some suggestion of a pelvic mass. However, deep palpation and vaginal examination were omitted because of the recent bleeding. Four well-healed scars of previous abdominal operations were present.

The temperature was 100°F., the pulse 100, and the respirations 20. The blood pressure was 120 systolic, 90 diastolic.

Examination of the blood showed a red-cell count of 4,730,000 with 14.3 gm. hemoglobin. The blood Hinton reaction was negative. The urine was normal.

On the fifth hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. MARSHALL K. BARTLETT: When we look over the history, there are several interesting points and several things that we should like to know. I assume that the periods from the age of twelve up to twenty-one, although profuse, were regular. There is no such statement, but irregularity is a point significant enough to have been mentioned if present.

The next interesting thing is that the patient was given three radium treatments at the age of twenty-one,—in other words, twenty-four years previous to entry,—following which she had no periods for six weeks; then, at about thirty, or fifteen years before entry, she had a tube and an ovary removed and another course of radium. This was followed by a longer period of amenorrhea, lasting seven months, during which she had hot flashes. Then, the menstrual periods returned, being regular although scanty until a year before entry, when they stopped. It would be interesting to know whether the patient had hot flashes during the time she was having those periods and during the last period of amenorrhea; the arithmetic does not come out right, to my way of thinking. She is said to have had the last period one year before entry, but amenorrhea for seven months and flowing for two months, stopping two days before entry, add up to only nine months. That is a minor point, but if one wanted to consider the possibility of pregnancy, the slight difference might be important. It is interesting that the last flow was continuous, whereas previously she had always had regular cycles.

What are the possible causes for this? I think that even on the basis of this meager physical examination it is possible to rule out a full-term pregnancy, and from the dates it would have to be full term. Was this a dysfunctional type of flow associated with endocrine imbalance? Certainly, there is a good background, with all the menstrual difficulty that is reported. Could the bleeding have been due to a polyp of the cervix or one of the endometrium? I think that the profuse bleeding just before entry would be unusual for cervical polyp, although possible, and that it could be associated with an endometrial polyp.

Could it be associated with the presence of fibroids? It could, and I see no way to rule it out on the basis of this information. The same thing applies to a benign ovarian cyst, if one was present. I do not see how one can be sure. Of these benign conditions, it seems to me that the

most probable one is the dysfunctional type of flow based on endocrine imbalance.

What could we say in favor of a malignant cause? Two points rather favor that. In the first place, the patient had had two courses of radium treatment a number of years before entry, which raises at least a theoretical possibility that she might have developed a malignant neoplasm on the basis of previous radiation. The other thing is the bleeding, which was different in type from what she had had before. It was continuous rather than intermittent. Could this have come from a carcinoma of the cervix? I believe that it could. Certainly, a carcinoma of the cervix can occasionally cause a sudden profuse hemorrhage. It is not common, but we do see it. Could it have been a carcinoma of the endometrium? I should think that it could, and if we give any weight to the previous radiation, the endometrium would be the logical place to look for it. The fact that the patient had cramps with the last episode that brought her to the hospital suggests something inside the uterus. How about a malignant ovarian cyst? Certainly, that can give slight continuous bleeding for two months. I think it would be unlikely to give profuse hemorrhage such as she had just before she came in. Could it have been a carcinoma of the tube? We know that that gives slight bleeding, with intermittent gushes, but I do not believe it would give a profuse type of hemorrhage.

We have all these possibilities, and I do not see that we have very much to go on in choosing between them. The points we have to work on are fairly small ones, but we must make a choice. It seems to me an even choice between a benign type of dysfunctional bleeding and bleeding on a malignant basis. Of the two, I am a little inclined to think that it was probably on a malignant basis, and of the various possible sites of carcinoma, the endometrium is probably the most logical choice.

DR. JACOB LERMAN: Could the patient have been radiated because they found a malignant ovary or something else at the time? Why was she given radium?

DR. BARTLETT: I should think that she was given small doses of radium to control the bleeding. If the ovary had proved to be malignant, it would have been more reasonable to go back and do a hysterectomy, with removal of the other tube and ovary as well.

#### CLINICAL DIAGNOSES

Functional uterine bleeding.  
Endometrial polyp.

#### DR. BARTLETT'S DIAGNOSIS

Carcinoma of endometrium.

#### ANATOMICAL DIAGNOSIS

Carcinoma of endometrium.

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The patient was examined vaginally under anesthesia. A normal cervix was found. The uterus was curetted, and a considerable amount of polypoid material, which grossly did not look malignant, was removed, but a frozen section showed that it was carcinoma. The curettage was then followed up by a complete hysterectomy, and a carcinoma of the fundus was found of quite undifferentiated character and a rather high degree of malignancy.

DR. LANGDON S. PARSONS: How much did the uterine radiation have to do with this?

DR. MALLORY: There is no way of telling. The one remaining ovary showed a single cyst, but was otherwise negative. The uterus was still quite small. There was no obvious extension of the tumor into the pelvis. It was not possible to feel the liver for metastases, because of adhesions of the omentum secondary to the previous operations, but at the end of the operation it seemed that a favorable result might be expected.

#### CASE 28072

#### PRESENTATION OF CASE

*First admission.* A forty-seven-year-old plumber was admitted to the hospital complaining of steady abdominal pain of twenty hours' duration.

The patient was fairly well until two years before admission, when he first noticed a steady, aching, low substernal pain and feeling of compression, which had persisted almost constantly since that time. The discomfort was usually worse at night and was sometimes relieved if the patient walked the floor. It was never severe enough to keep him awake, and was not influenced by exertion, breathing or swallowing. At approximately the same time, he began having dull headaches, became weak and tired, and developed nocturia (once). He entered an outside hospital for a checkup, and was told that his blood pressure was "276." After discharge, he continued to work, and was fairly well until twenty hours before admission, when while eating a sandwich and drinking coffee at 10 p.m., he was suddenly seized with a severe steady pain beneath the xiphoid; this soon radiated through to the back and up between the shoulder blades. He felt nauseated and vomited

a small amount of food. The pain increased in severity, and half an hour after its onset he attempted to "walk it off." He then experienced a severe cramp in the back of the right leg, which remained until he stopped walking. It failed to return, thereafter, but the subxiphoid epigastric pain continued in spite of two hypodermic injections given by his physician. He finally fell asleep about 4 a.m., but was awakened at 7 a.m. by the same pain. Throughout the morning and afternoon before admission, the pain continued while he restlessly paced the floor.

Physical examination revealed a well-developed and well-nourished man who was walking restlessly in acute distress because of severe, steady epigastric pain. He was unable to lie flat on his back, writhing constantly. He felt somewhat better lying on his side, sitting or standing erect. There was no sweating, pallor or cyanosis. The fundi showed "moderate arteriosclerosis." The teeth were carious. The lungs were clear and resonant throughout. The heart was slightly enlarged to the left, the pulse full, 85 per minute, and regular. There was a faint systolic murmur at the apex. The aortic second sound was louder than the pulmonic. The sounds were of good quality. No friction rub was heard. There was marked tenderness, without spasm, high in the midepigastrium, but there were no masses or palpable viscera, and no tympany or abnormal peristalsis. No other positive findings were elicited.

The temperature was 99.8°F., the pulse 85, and the respirations 20. The blood pressure was 180 systolic, 110 diastolic.

Examination of the blood showed a red-cell count of 4,500,000 with 100 per cent hemoglobin, and a white-cell count of 14,300 with 90 per cent polymorphonuclears. The urine and stools were normal. The phenolsulfonphthalein urinary-excretion test showed 25 per cent excretion in fifteen minutes and 60 per cent in one hour. The sedimentation rate ranged between 0.7 and 0.8 mm. per minute. The serum nonprotein nitrogen was 21 mg. per 100 cc. The blood Hinton reaction was negative. An electrocardiogram showed a ventricular rate of 80, with normal rhythm, a PR interval of 0.19 second, diphasic T<sub>1</sub>, low T<sub>2</sub> and late inversion of T<sub>4</sub>, with left-axis deviation. Roentgenograms of the abdomen with the patient lying down showed one loop of slightly dilated, air-filled small intestine in the left upper quadrant. There was an area of poorly defined decreased density overlying and extending to both sides of the fourth lumbar vertebra. Films in the upright position showed no evidence of free air below the diaphragm. The psoas shadows were clearly

outlined. Films of the gall-bladder region with Graham test showed no gallstone. Chest films, both anteroposterior and lateral, revealed a markedly tortuous aorta. Intravenous pyelograms nineteen days after admission showed that there was prompt excretion of poorly concentrated dye on both sides, but the concentration on the right side was not sufficient to outline the kidney pelvis. There were no air-filled dilated loops of bowel. A gastrointestinal series was negative.

For the first four hospital days, the patient ran a slightly elevated temperature (100 to 101°F.), pulse (90 to 95) and respirations (22 to 25), but for the remaining five weeks his chart was flat. The abdominal pain persisted for six days, required heavy morphinization, and then gradually decreased. In this interim, its main focus migrated somewhat from the midepigastrium to the right upper quadrant, and then, as it slowly disappeared, to both lower quadrants. The blood pressures in the arms and legs were about equal at 180 systolic, 100 diastolic. On the fourth and fifth days of the illness, the urine contained 40 and 20 red blood cells per high-power field in the sediment, respectively; thereafter, it was normal. The electrocardiogram on the second hospital day showed low T<sub>1</sub>, T<sub>3</sub> and T<sub>4</sub>, with slight left-axis deviation, and on the fifth day, low T<sub>1</sub>, with a late inversion of T<sub>4</sub>. Convalescence was uneventful, and the patient was discharged on the forty-first hospital day.

*Second admission* (two and a half months later). Following discharge, the patient remained at home on a careful rest regime for six weeks. He then began doing light work, and seemed well until one week before admission, when substernal pain and a sense of chest constriction reappeared, apparently unrelated to exertion, but relieved within half an hour by nitroglycerin.

Physical examination was unchanged from that on the first entry, except that the heart was enlarged 2 cm. beyond the midclavicular line and the blood pressure was 220 systolic, 140 diastolic, in all extremities. The temperature, pulse and respirations were normal. Both urine and blood examinations were negative except for a slightly elevated white-cell count, ranging from 8000 to 13,000. The electrocardiograms were essentially unchanged, but a review of the x-ray films of the chest showed a definite dilatation of the aortic arch when compared with films taken two years previously in the Out Patient Department.

While in the hospital, the patient had a severe one-and-a-half-hour attack of chest pain, which radiated down the left arm and was only partially relieved by morphine. The left radial pulse

was definitely weaker than the right, and the blood pressure, in the right arm was 170 systolic, 120 diastolic, whereas that in the left was 120 systolic, 80 diastolic. There were no residual symptoms following this episode. The next day, the blood pressures in the extremities were about equal at 210 to 240 systolic, 150 to 180 diastolic. The patient was discharged on the twenty-fourth hospital day.

*Third admission* (nine months later). Following discharge, the patient had been well, using nitroglycerin occasionally for chest pain. He had rested for six months, after which he had been doing sedentary work. Twenty-four hours before entry, while working, he experienced the rapid onset of severe pain in the left arm, with an associated mild oppression in the upper sternum and pain on both sides of the neck. This lasted one hour, and one hour later it reappeared. He took a nitroglycerin pill without benefit, and the next day entered the hospital, where an electrocardiogram showed a ventricular rate of 80, with normal rhythm, T<sub>1</sub> inverted, T<sub>2</sub> diphasic, T<sub>3</sub> upright, T<sub>4</sub> inverted, R<sub>4</sub> present and moderate left-axis deviation. Five days later, T<sub>2</sub> was inverted, T<sub>4</sub> more deeply inverted, and T<sub>1</sub> slightly more so. Funduscopic observations revealed several fresh hemorrhages in both fundi. The physical and laboratory findings were otherwise unchanged. The patient remained in the hospital for eight days, during which his chart was normal.

*Final admission* (four months later). Eight hours before admission, the patient had a sudden attack of substernal pain radiating down both arms and into the neck, following the ingestion of two glasses of beer. On examination, he was in obvious pain, breathing rapidly and groaning from time to time. There were a few crackles at the left base posteriorly. The heart sounds were distant and not of good quality; the pulmonary and aortic second sounds were equal. The blood pressure was 194 systolic, 118 diastolic. An electrocardiogram showed no essential change from the last, except biphasic instead of inverted T<sub>1</sub> and T<sub>2</sub>. The white-cell count was 15,000. The electrocardiogram two days later showed no change. The patient developed a gallop rhythm, a fall in systolic blood pressure to 158, pallor, sweating and cold extremities, and showed crepitant rales and wheezes at both lung bases, an enlarged slightly tender liver, without edema of the sacrum or the extremities, and distention of the neck veins. He was given oxygen and morphine, and was digitalized. On the third hospital day, he suddenly failed, and died within thirty minutes.

#### DIFFERENTIAL DIAGNOSIS

DR. ALFRED O. LUDWIG: In this case, we are confronted with a man who was obviously suffering from hypertension, and we must decide what was the nature of the episodes of severe pain that finally led to his death. Not many conditions cause pain severe enough to be unrelieved by two injections of morphine. One immediately thinks either of extensive cardiac infarction or of some other serious vascular accident. I believe that the radiation of the pain, its character, his efforts "to walk it off" and the occurrence of cramps in the legs are all of great importance in the differential diagnosis.

In the first physical examination, the significant facts are the relatively slow and regular pulse, the apparent fall in blood pressure and the absence of a pericardial friction rub. These findings by no means finally exclude the presence of coronary occlusion. It would be somewhat unusual not to have more shock in the presence of coronary infarction of the severity indicated by the degree of pain that this man had. The absence of spasm in the epigastrium is evidence against such notable peritoneal irritation as would certainly follow any serious abdominal emergency like a ruptured viscus or acute inflammatory disease in this region. The slight elevation of the temperature is quite consistent with either coronary occlusion or any other severe vascular lesion.

The patient had moderate leukocytosis on this admission and a moderately elevated sedimentation rate, and these are of little help in differential diagnosis. The nonprotein nitrogen and renal-function tests indicate that no serious impairment of renal function had yet taken place as a sequel to the hypertension. The changes in the electrocardiogram are consistent with hypertensive heart disease with coronary involvement, but do not indicate the presence of acute occlusion. The x-ray films help us in ruling out a ruptured viscus in that they failed to show gas under the diaphragm, and also dispose of the gall bladder as the seat of this man's symptoms. One would like to know more about this area of decreased density overlying the fourth lumbar vertebra. Was there any evidence of erosion of these vertebrae? Could this mass represent dilatation or aneurysm of the abdominal aorta? The tortuosity of the aorta, as demonstrated by the chest films, is a further important point in the differential diagnosis, and further directs suspicion to this vessel. I do not believe that we can draw any valid conclusions from the intravenous pyelograms at this juncture. The gastrointestinal series serves to exclude the stomach as the seat of the lesion.

The most important statements in the next paragraph concern the course of the pain, which continued to be severe for six days, and the appearance of red blood cells in the urine, which suggests to me the possibility that some impairment of renal circulation may have developed. The second electrocardiogram does not convince me that coronary occlusion was present.

The pain returned soon after discharge, this time being more prominent in the chest. Physical examination on the second admission showed a rise in blood pressure over the previous reading. Most significant is the increase in dilatation of the aortic arch in the films taken at that time. The course in the hospital was notable for the occurrence of chest pain, with radiation down the arm, and diminution of the left radial pulse and of the blood pressure in this arm, suggesting impairment of the circulation to this arm, perhaps due to a lesion in the aortic arch.

On the third admission, there had been further extension of the process that had first appeared on the previous occasion and caused a fall in blood pressure in the left arm. The electrocardiogram suggested that there was definite involvement of the coronary tree, and the progressive changes in the T waves strengthen this belief. The fundal hemorrhages may have been secondary to the hypertension or due to interference with circulation. The symptoms on final admission spell further impairment of coronary circulation and rapid heart failure, with pulmonary and hepatic congestion, quickly followed by fatal circulatory collapse.

As I see this case, there is only one condition that satisfactorily explains all the signs and symptoms. I believe that this man had extensive arteriosclerosis of the entire aorta, and that he had successive episodes of dissection of the aortic wall secondary to small rents in the inner coat of this vessel. The first of these I believe took place in the lower thoracic or upper abdominal aorta. The dissection of blood down between the coats of the vessel temporarily interfered with circulation in the legs, as evidenced by the cramps on walking, and later with the renal blood supply, as shown by the appearance of hematuria. The second episode must have involved the aortic arch, with the dissecting blood constricting the mouths of the vessels arising from the arch that supplied the left upper extremity. The third episode may have represented further extension of the dissecting process in the arch to encroach on the coronary mouths and hence leading to coronary insufficiency. Finally, there was further extension in

the region of the arch, with further coronary constriction, cardiac collapse and death.

Most of the cases of dissecting aortic aneurysm that we have seen in this hospital have been acute and followed shortly by death. It is quite unusual for this condition to have so long a course as in this man, but such cases have been described. The severe character of the pain and its radiation to the back and shoulders, and later to the neck and arms, are quite characteristic of dissecting aortic aneurysm. When this condition involves the arch or thoracic portion of the vessel, it is commonly confused with coronary occlusion. In such cases, as in this, the absence of the characteristic electrocardiographic changes associated with acute coronary occlusion is a very helpful differential point. When the abdominal aorta is involved, an acute abdominal emergency may be simulated. I believe that the post-mortem examination will disclose the presence of cardiac hypertrophy secondary to the hypertension, extensive sclerosis of the entire aorta, with multiple dissecting aneurysms encroaching on the vessels of the arch, the coronary arteries and possibly the renal arteries. I do not believe that syphilis played any part in the production of the lesion in this case. It is very rare to obtain negative serologic findings in the presence of a syphilitic aortic aneurysm.

#### CLINICAL DIAGNOSES

Acute coronary occlusion.  
Hypertensive and coronary heart disease.

#### DR. LUDWIG'S DIAGNOSES

Essential hypertension.  
Hypertensive and coronary heart disease.  
Arteriosclerosis of aorta, with dissecting aneurysms of arch and thoracic and abdominal portions of aorta.

#### ANATOMICAL DIAGNOSES

Dissecting aneurysms of aorta, old, with rupture into right iliac artery, and fresh, with rupture into pericardium.  
Hemopericardium, with cardiac tamponade.  
Media necrosis aortica cystica.  
Compression of right renal artery, with atrophy of right kidney.  
Hypertrophy of left kidney.  
Nephritis, chronic vascular.  
Cardiac hypertrophy, hypertensive type.  
Arteriosclerosis, generalized: marked in aorta and coronary vessels.  
Bronchopneumonia, slight, of right lower lobe.

## PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY. Dr Ludwig has predicted with great accuracy our post mortem findings. At the time of the patient's first entry, there was lively discussion in regard to the diagnosis. Several persons, including Dr Wyman, Richardson and Dr. Edward F. Bland, stood out for dissecting aneurysm. A surgical consultant, however, was all for immediate transfer to the Surgical Service and exploratory laparotomy, although he never committed himself on paper to the precise type of surgical abdomen that he expected to find. Dr. Richardson, who was in charge of the service at the time, firmly refused to permit the transfer and remained unshaken in his diagnosis of dissecting aneurysm, even when the patient proceeded to make an unexpected complete recovery. On the second and third admissions, the symptoms were more limited to the cardiac area, and the events of the first admission were lost sight of, so that the final diagnosis on the death report was acute coronary occlusion, associated with hypertensive heart disease. On the final admission, however, Dr. Paul D. White again raised the question of dissecting aneurysm.

At the post-mortem examination, we found two separate dissecting aneurysms, clearly of different ages. The older one, which was obviously responsible for the events leading to the first admission, began with a horizontal tear on the anterosuperior aspect of the arch just distal to the subclavian artery at a point 9 cm. above the aortic valve. This led into smooth, endothelialized fat, which lay within the media of the vessel and nearly, but not quite completely, surrounded the

vessel. It had extended downward the entire length of the thoracic and abdominal aorta into the right common iliac artery, where it had reruptured through into the lumen of the latter vessel. This explains the temporary cramps in the right leg and their disappearance with the return of circulation. As evidence of the chronicity of this process, the lumen of the aneurysm was completely endothelialized and was, in fact, dotted with numerous small, bright-yellow plaques of atheroma. A second independent and evidently much more recent dissecting aneurysm began with another horizontal tear of the aortic intima 3 cm. distal to the first one but on the right posterior surface. In this case, the aneurysm had extended backward instead of forward down the ascending aorta to the annulus of the aortic valve, thus involving the mouths of both coronary arteries and that of the innominate artery. Three centimeters above the aortic valve, the outer layer had ruptured into the pericardium, which was distended with 500 cc of partly clotted blood. This aneurysm was obviously much fresher than the other, since it showed no endothelialization. We did not succeed in finding any trace of a third episode, such as Dr Ludwig suggested. Therefore, it is quite possible that the dissection of the second aneurysm occurred in more than one stage. It was of interest that the right kidney was only half the size of the left, and the right renal artery seemed considerably narrowed by the external pressure of the aneurysmal fat. The heart, as one would have expected, was considerably hypertrophied, and showed fairly marked atherosclerosis of most of the coronary branches, with numerous patches of narrowing but no foci of occlusion.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston, Massachusetts.

## THE RESPONSIBILITIES OF HOSPITALS IN MATTERS OF CIVILIAN DEFENSE

A LARGE majority of the hospitals in Massachusetts have been asked to contribute directly, in one way or another, in the problem of civilian defense. Those that are to be used as emergency hospitals in the event of disaster must provide for adequate supplies and equipment and must so organize their professional and nonprofessional staffs on eight-hour or twelve-hour shifts that teams for the proper care of casualties will be available at a moment's notice. And those that are to serve as base hospitals must be prepared to receive and care for the large numbers of patients who will be evacuated, as soon as possible, from the emergency hospitals. Furthermore, Governor Saltonstall, in his proclamation dated January 8, ordered that "hospitals . . . shall be immediately

equipped for blackout." This does not mean that the order applies only to those hospitals that are to be used as emergency and base hospitals but rather to *all hospitals* within the Commonwealth, and the need for such a provision is obvious.

Although much has been asked of the hospitals in the emergency, it is no more than, or as much as, has been demanded of those who work in close association with them. Physicians have willingly responded to calls to military service, to the examining and advisory boards of the Selective Service System, to induction boards, to federal consulting boards and to the central, regional and local organizations of the Medical Division of the Massachusetts Committee on Public Safety. This exemplary response of the medical profession should serve as a pattern for hospital authorities. By promptly and efficiently meeting their responsibilities, they, too, can contribute wisely and effectively to the problems that confront the Commonwealth at this time.

## THE SCIENCE OF NUTRITION

THE world will always have to be patient with those who claim, and sympathetic with those who are required, to speak the truth, the whole truth and nothing but the truth, for as Anne Lindbergh observed, "To write or to speak is almost inevitably to lie a little." Our words fit our ideas so loosely. Even the mathematically efficient precision of modern gunnery must be concluded with the phraseology that the marksmanship was "poor" or "good," and in the case of the shell that struck the magazine of the battleship *Hood* the marksmanship was rightly termed "unfortunate." What would William of Orange say to the American columnists who keep repeating that England has not been invaded since the day of William the Conqueror? They have said it so often that many people now believe it to be a fact. Our minds move in tiny circles or leap great gaps of time or space with equal facility. Somehow, we rely on others to keep us from going too far astray.

On whom are we relying to keep our nutritional appraisals and advices within bounds? It is obvious that our nutritional status may not be at an

optimum because nobody knows what the optimum should be. It may even be admitted that there is a serious degree of malnutrition in this country, without throwing too much fat on the fire of the vitamin vendors. The stories of office girls who become listless when they are deprived of their thiamin, however, are reminiscent of the testimonials for Lydia Pinkham's vegetables, or whatever they were. Clinically visible nutritional deficiencies now attract our attention more readily, to be sure, but they are oftener secondary to alcoholism, dementia or advanced organic disease than to a lack of knowledge or economic resource. The gross nutritional lacks of twenty years ago have all but disappeared. What has become of the rickety baby? The adolescents of today are obviously larger and stronger than their parents are or ever were. For a nutritionist<sup>1</sup> to state that our food ways "are worse today than they were in 1914" seems ridiculous. Casual reading of some of his admonitions indicates that we have been going down the wrong road, or even moving backward, but when we see that they are based, among other things, on "many recent nutritional surveys including the extensive governmental study of consumer purchases conducted by the Bureau of Labor Statistics, the Bureau of Home Economics and the National Resources Committee," we begin to see the light.

The Science of Nutrition is being moved into the same apartment with Adequate Medical Care. It can pay the rent; it needs a better home and so is being moved. But it is a large family, which cannot possibly be completely housed even in spacious governmental bureaus; friends and relatives must be left behind who will continue to work under present conditions and with present scientific standards. There is going to be some temptation for those who have acquired new surroundings and new friends to forget their former associates, to forget the standards under which they previously lived and worked. There is going to be some pressure for them to keep up with the Joneses in the new neighborhood, where it is doubtless assumed that diets can be balanced with the same facility as budgets. The House of

Delegates of the American Medical Association has called at the new apartment and paid its respects in the form of a series of resolutions adopted at the Cleveland session, but the *Journal of the American Medical Association*<sup>2</sup> has also taken notice of the inspired character of some of the initial efforts. The medical profession may be counted on to back up any statement or program that is warranted by facts or good evidence, or even that is not too greatly exaggerated. Exaggerations, however, are seized on by publicists, who allow their stories to carry unintended implications, and this does the Science of Nutrition no good.

#### AN APPRECIATION

FRANK BURR MALLORY

1862-1941

It would appear to be a work of supererogation to discuss the record of Frank Mallory in the city and state that were his for fifty years, and yet he led an almost cloistered existence, which limited the opportunity to meet and know the man. Until the last year of his life, he was doing progressive work in an institute that properly bore his name, since he had demonstrated in his department that a lowly "city hospital" could be made to rival endowed research institutions. It is not my intent to write an obituary but rather an appreciation of a truly great man with whom it was my good fortune to be associated for many years.

One of Dr. Mallory's greatest contributions to the progress of medicine was undoubtedly his work on stains. He spent a year with Ziegler and Chiari in his early days in laboratory medicine, during the period when medical science was coming into flower in the Golden Age of German medicine. As one looks back to that period, it is remarkable to note the coming together of a literal constellation of geniuses, who suddenly appeared and co-operated in the launching of the new scientific medicine. Koch, Abbé, Weigert, Ehrlich and their colleagues, notably the group of fortunate bacteriologists who were in a position to take advantage of the opportunities presented by the new science, were destined to live in medical history.

Ziegler and Chiari were the pathologists of the group, giving special attention to the newer developments of pathologic histology. Weigert had focused attention on the aniline colors, which were an outgrowth from the English Perkins's ink, and microscopic pathology, crude up to then, became a highly specialized field that opened up new vistas in practical medical progress as well as in the field of pure science. Of Dr. Mallory's work in this

FRANK BURR MALLORY

field, Ewing has said, "The older pathologists had largely exhausted the possibilities of pathologic anatomy and histology, but it remained for Mallory, Ramon y Cajal and del Rio Hortega to carry histopathology to its highest development, and to make contributions beyond the reach of other methods."

These masters developed technics by which special tissues could be differentiated through tinctorial reactions. Dr. Mallory's interests began with efforts to more sharply label intercellular substances. Collagen, myoglia and neuroglia fibrils were in his special field of endeavor, and he first demonstrated and described fibroglia fibrils. His next interest was in the application of the new technic to the tracing of origins of cells from embryonal sources, in an effort to classify new growths more exactly. The results of his studies in these and other histologic fields were to revolu-

tionize laboratory practice in America. The laboratory horse-and-buggy period, referred to scornfully by the superior biologic chemist as the "hematoxylin-and-eosine period," was to come to an end. And yet it did not come to an end, or at least hematoxylin did not. Dr. Mallory was among the first to recognize the remarkable character of hematoxylin as a stain. His most selective staining method is that using phosphotungstic acid hematoxylin, and in his later years he was able to develop with hematoxylin a stain for traces of copper in tissues, more delicate than any chemical test. Morphology, banished as a dead subject, has come into its own again in its ability, with tinctorial aids, to do more exacting work than is possible by biochemical methods alone—to identify cells and observe by tinctorial procedures the chemistry of the individual cell.

Dr. Mallory's staining methods were to make his name familiar to laboratory men in all quarters of the globe. The brilliant results obtainable with his stains were arrived at only through exhaustive trial and error until the perfect method was achieved. He would work for months following leads that suggested the possibility of more specific differentiation of tissues or tissue products.

The sheer wizardry that can convert a commonplace coronary lesion, as seen in a section stained with hematoxylin and eosin, into a thing of beauty and distinction, as seen in a section stained by Mallory's aniline blue method, is alluring. It has a touch of Cinderella magic. The lipoid cells cease to be disembodied nuclei and become tangible objects with pink lacelike meshworks enclosing the spaces that had been occupied by the droplets of cholesterol esters. The collagen is a brilliant blue, the fibroglia fibrils are distinct, and the unstriped muscle of the media, bright red, becomes a tissue of quality instead of a bastard relative of the connective-tissue series. The fibrous tissue differentiates itself into young fibroblasts, older collagen-producing cells and frank hyaline scar tissue. With experience, one could almost write the natural history of the lesion without further information.

In this connection, a story told by Elliott Cutler is interesting. Dr. Cutler was working in Krehl's laboratory. The great man made his grand rounds of the laboratory at intervals. The worker stood rigidly at attention, facing his bench and the window, while the professor walked through behind him. If the master condescended to an interest in his work, the student was permitted to unbend and show his wares. Working next to Dr. Cutler was a graduate German student, Professor Marchand's son, who was doing an *Arbeit* on the brain. His sections were poor and badly stained

Dr. Cutler unearthed in the basement an abandoned paraffin microtome, which was finally coaxed into action. The resulting sections, which were fair, were stained by Mallory's phosphotungstic acid hematoxylin. When the great man made his next visit, he stopped at the student's bench, where he had never stopped before. There were explosive outbursts of "*Wunderbar! Wunder-schön!*" as the student explained the provenance of this remarkable exhibit. Dr. Cutler was called on, and told of his work with Dr. Mallory. "*Mallori, Mallori,*" exclaimed the professor, "I thought that he was an Italian."

Dr. Mallory's publications, apart from those on staining technic, were many and varied. His studies cleared the foggy atmosphere that surrounded the complicated pathology of typhoid fever. The paper on this subject, read before the Philadelphia Pathological Society, was illustrated by a series of eight magnificent color plates of drawings that might have served as a model for future medical illustration. However, the cost of such illustrations was almost prohibitive, and they were open to the criticism that, although they represented efforts at objective reproduction by the artist of actual microscopic fields, their delineation by human hands subjected them to possible bias, not with intent, but perhaps as the result of wishful thinking. For these reasons, Dr. Mallory turned to photographic reproductions and, in characteristic fashion, made himself a master of photomicrography. In his publication on the subject with Miss Leavitt, he disclosed the secrets of the art: "The first and greatest secret of good photomicrography is perfect sections, perfectly stained. . . . The second important point is choice of field." How often has he stressed the necessity of spending almost more time on the choice of fields for illustrations than on the writing of a paper! The lessons he taught in this respect resulted in a high quality of illustration in papers by his students, and elevated the level of scientific illustrations in American medical journals.

His studies of typhoid lesions brought out the activities of phagocytic cells, which arose from the endothelium of blood and lymph vessels and which he called endothelial leukocytes. The sources of these cells were widespread, as was their distribution, although the most important origin was the lymph and blood systems of the intestine, the seat of the primary focal infection. In this and further studies, it was recognized that the functions of the endothelial phagocytic cells were distinguished in general from those of the polymorphonuclear leukocytes. Although they did engulf certain bacteria (particularly tubercle bacilli), phagocytosis by the endothelial cells tended to be limited to other cells, particularly red blood cells and lymphocytes.

These studies included observations of mitoses in the endothelium of lymph and blood vessels and the migration of the endothelial leukocytes from the vessels into surrounding tissue. It was further recognized that many of the phagocytic cells passed through the liver and the lungs and thus into the systemic circulation.

Though Metchnikoff had developed his "theory of phagocytes" some years before this time, Mallory's studies of phagocytosis by cells of endothelial origin in human tissues were among the earliest published, were remarkable for their thoroughness of observation, preceded the studies of vital and supravital staining by colloidal dyes, and long antedated the Aschoff concept of the reticuloendothelial system.

The abundant pathologic material from the South Department of the Boston City Hospital was the basis for a series of studies of the pathology of the contagious diseases. A chapter on the pathology of diphtheria was contributed to the Cambridge University *Diphtheria*, edited by Nuttall and Graham-Smith, and papers were written on scarlet fever, measles and whooping cough.

The use of differential stains in determining the embryonal sources of tumor types was thoroughly investigated over a period of years, and the work formed the basis for the Middleton-Goldsmith Lecture of the New York Pathological Society for 1908. This and later papers on the microscopic anatomy and differentiation of cancer established Dr. Mallory's reputation as a national authority on tumors. With Dr. Gaylord, Dr. Weil and a few others, he formed the American Association for Cancer Research. The same group was responsible for stimulating the Congress of American Surgeons to develop interest in the education of the public with reference to cancer. Their action led ultimately to the formation of the American Society for the Control of Cancer.

In 1906, when the Harvard Medical School moved into the new and spacious buildings on Longwood Avenue, Dr. Mallory, under the heading "The Present Needs of the Harvard Medical School," appealed for endowment, not so much for the laboratory branches, although inadequate salaries were preventing men from entering these fields, but for clinical instructors "whose chief interests shall be teaching and scientific medical investigation."

At a time when the older conservative pathologists insisted that the Association of American Physicians was the national pathological society,

Dr. Mallory was one of the leaders in forming the American Association of Pathologists and Bacteriologists and was backed by the younger men in Boston. He took over the *Journal of Medical Research* on the death of Dr. Harold Ernst in 1923, and became its editor-in-chief. When the journal became the *American Journal of Pathology* and was made the official organ of the American Association of Pathologists and Bacteriologists, he remained as its editor-in-chief until 1940.

There arose a demand for a text on laboratory methods, which Dr. Mallory's training and experience and that of his colleague, Dr. Homer Wright, fitted them to satisfy. The familiar *Pathological Technique* was the answer, and has been the accepted authority on the subject since that time. The book represented the result of years of effort in the actual working out of laboratory procedure. With the pathologic material supplied by a large city hospital, supplemented by material from a large semipublic hospital, and added to by problem material referred to him from many sources, it was possible to determine the practical value of standard tests and to develop new procedures, which were improvements on the old or which entered new fields. Under the methods of laboratory study in the Boston City Hospital laboratory, which was early staffed with one or more residents and included a group of graduate students, exhaustive series of applications could be made of a test under investigation. In 1914 was published Dr. Mallory's *Principles of Pathologic Histology*, "which for reliability and detail has never been excelled in any language."

Dr. Mallory took great pride in the technic practiced in his laboratory. He used to refer with a chuckle to the custom of Chiari, who would rap the knuckles of his students if he caught them cutting thin sections. "*Nicht so dünn, nicht so dünn*" was his constant cry. Which reminds one of a famous American expert who is said to have announced, "Give me a good thick section of tissue fixed in formalin and stained with hematoxylin and eosin, and I am content," forgetting the amazing experience and expertness permitting him to make diagnoses under a technical handicap that would floor most if not all his colleagues.

Genius is the infinite capacity for taking pains. No person who was familiar with Dr. Mallory's studies on cirrhosis of the liver could question his tenacity, the exactness of his technic or the thoroughness with which he exhausted all the available experimental fields. His studies of the histology of cirrhosis disclosed the hyaline degeneration of liver cells, which is the distinguishing mark of alcoholic cirrhosis. Because his studies were

among the first by modern methods, it was his duty for thirty years to prove that ethyl alcohol was not the cause of the disease. As one genus of animals failed to respond, he turned to others, including many genera that had not before been used for laboratory purposes. He demonstrated, with Parker and Nye, that excess copper was the cause of pigment cirrhosis.

His manner of approach to a study of pathologic processes is illustrated in his introduction to a paper, "Cirrhosis of the Liver: Five different types of lesions from which it may arise." Cirrhosis, which becomes clinically manifest only in its later stages, had been studied almost wholly in its advanced, sclerotic form. Of this tendency, Dr. Mallory said: "In some organs the late stages of certain lesions have received more attention than the beginnings of these lesions. The emphasis has been placed on the wrong end of the process. . . . In order to understand a pathological process, it is necessary to find and study its beginning and to trace its biological development." This paper, beautifully illustrated, was read before the Johns Hopkins Medical Society. More recent studies have not improved on Dr. Mallory's classification of the cirrheses. He carefully refrained from limiting the causation of cirrhosis to the mechanisms responsible for the five types described. Recent demonstrations of the production of experimental cirrhosis by many agencies justify this caution.

Dr. Mallory lived an ascetic life. His training and experience taught him that the only way to do superlative work was to make that work an obsession, to avoid society and extracurricular demands. It is related that at a faculty function shortly after the birth of his older son, the irrepressible Dr. Arthur ("Patsy") Wentworth arranged with the faculty members that individually they should approach Dr. Mallory with a full glass of champagne and drink the health of the infant, with a hint at bottoms up. It is recorded that Dr. Mallory finished the ordeal with some of its original content of champagne still in his glass.

Austerity is almost a requisite in the public's mental picture of a scientist. To those who did not know Dr. Mallory, he appeared to be a perfect example of the genus, and yet he was intensely human. He had two sons and an army of adoptive sons, to use Sabatini's word, which I like, because it implies mutuality. He was as much interested in the young men who went through his laboratory as though they were his sons. The neophyte who was careless in thought or slovenly in action would feel the sharp edge of his tongue. But, once he had indicated his willingness, his intelligence and his capability, he had

in Dr. Mallory a friend who would help fight his battles. As Dr. Mallory said in his fifty-year class record (1886-1936), "Aside from the problems of my own line of work, one of my greatest pleasures has been in training young men and women in pathology and in seeing what they could make out of themselves under proper encouragement and stimulation; in other words, in getting them to do their own thinking and to work out their own salvation."

Dr. Mallory delivered a Harvey Lecture (1912) ("The Infectious Lesions of Blood Vessels"), the Mellon Lecture for 1925, the Hanna Lecture for 1925 ("Hemochromatosis and Chronic Poisoning with Copper") and the Shattuck Lecture for 1932 ("Cirrhosis of the Liver"). He was awarded the George M. Kober Medal for outstanding service in pathology by the Association of American Physicians. He was the third recipient of the gold-headed cane (following Dr. William H. Welch and Dr. Theobald Smith), given by Dr. Ernst to the American Association of Pathologists and Bacteriologists and awarded by them as a mark of distinguished service. He was a member of the Deutsche Pathologische Gesellschaft and of the Royal Medical Society of Budapest, an honorary member of the Pathological Society of Great Britain and Ireland and a fellow of the American Academy of Arts and Sciences. He was given honorary degrees of Doctor of Science by Tufts College and Boston University. In spite of his many honors, he never posed as a great man and was always available for counsel. The contrast between the autocratic practices in vogue in German laboratories and the procedure in Dr. Mallory's laboratory was great. He "sporting his oak" only when some trying bit of experimental work that would not brook interruption was under way. Remarkable to his friends was his ability to turn out progressive research under the constant interruptions that were a part of his daily life.

There was nothing of the "picturesque personality" in his make up. Diletantism, with all it implied, was abhorrent to him. He was inclined to be critical in his early days of those whom Weigert called Mr. Modifiers—Jones's modification of Brown's modification of Robinson's stain. He came, however, to appreciate that the modifiers were indicators of the progressive character of scientific medicine. They were emblems of dissatisfaction with things as they were at the moment, and marked a healthy state of discontent. He had great dislike for what he called "armchair pathologists," who capitalized the work of others, or depended on what Wright referred to with a sniff as "closet researchers."

Dr. Mallory not only placed his young men in positions for which they were fitted, but followed with fatherly interest their upward progress through the years. And the progress of the men who worked in his laboratory was quite constantly upward. Of professorial rank alone, forty men in American and Chinese schools were or are graduates of the laboratory, and nineteen of them were or are engaged in teaching pathology. Their training in the laboratory fitted them to direct similar work in any medical institution or to start with superior preparation in any of the clinical branches. When plans for a piece of research were in question or difficulties arose in the diagnosis of rare specimens, resort could be had to "The Chief" with assurance of his scientific interest and help. He retained up to the end an undiminished enthusiasm. When something new was brought to him or even something old in the preparation of which good work had been done, his eyes would light up with interest. His critical approval of a piece of original work—the metaphoric tap on the shoulder—was an accolade to be sought for and cherished.

This was a man!

T L

## MEDICAL EPONYM

### MOEBIUS'S SIGN

The first mention of this sign was made by Moebius in a review of Pierre Marie's *Contribution à l'étude et au diagnostic des formes frustes de la maladie de Basedow* (Paris, 1883). The review appeared in Schmidt's *Jahrbucher der inneren und auslandischen gesammten Medicin* (200: 98-100, 1883). A portion of the translation of the former follows:

Von Graefe has said that lessening or abolition of the synergetic movement of the upper lids in raising and lowering the eyes is pathognostic. The reviewer has failed to find Graefe's symptom in a series of cases including some with and some without exophthalmos. He not only disbelieves in its pathognostic character, but considers it rather rare. On the other hand, the reviewer has recently observed a disturbance of convergence in two patients with Basedow's disease, both of whom had a moderate bilateral exophthalmos of equal degree. If the patient was asked to fix his vision on the examiner's finger, both eyes looked to the right or to the left. That is, the patient fixed with one eye and the external muscles of the other eye contracted consensually. On monocular examination, both internal recti functioned normally. In a third patient with exophthalmos, the symptom was absent. Whether the phenomenon is directly dependent on the exophthalmos is uncertain.

The subject was again discussed, and observations in eight additional cases were reported, in an

article, "Über Insuffizienz der Convergenz bei Morbus Basedowii [Convergence Insufficiency in Basedow's Disease]," which was published in the *Zentralblatt für Nervenheilkunde, Psychiatrie und gerichtliche Psychopathologie* (9: 356-358, 1886).

### COMMITTEE ON MATERNAL WELFARE

#### CAUSES OF MATERNAL DEATH IN MASSACHUSETTS DURING 1940 (*continued*)

##### ALBUMINURIA, TOXEMIA AND ECLAMPSIA

Twenty-four cases are classified under albuminuria, toxemia and eclampsia.

*Undelivered cases.* Six patients died undelivered.

Two weeks before term, one patient had a systolic blood pressure of 170, with a large amount of albumin. Hospitalization was advised and refused. The following day, the physician was notified that the patient was having difficulty in breathing. When he arrived, she was dead. Cerebral hemorrhage may have been the immediate cause of death.

Another patient had had no prenatal care, and convulsions were present when she reached the hospital. The systolic blood pressure was over 200. There was a large trace of albumin in the urine. No attempt was made to induce delivery, and the patient died shortly thereafter.

The next case occurred in a twenty-seven-year-old primipara who had had very poor prenatal care. When she arrived in the hospital, she had a blood pressure of 190 systolic, 110 diastolic. She had a large amount of edema. Convulsions appeared, and the patient was treated medically. No attempt at delivery was made.

The next patient, a multipara in her thirteenth pregnancy, had had no prenatal care. The blood pressure was 252 systolic, 152 diastolic. The patient died after receiving a few whiffs of chloroform for an emergency cesarean section.

Another patient died shortly after she reached the hospital. She was comatose when she arrived, and was treated with Veratrone and artificial respiration but never regained consciousness. This patient was very poorly treated during pregnancy. Autopsy showed that the immediate cause of death was hemorrhage about the medulla.

The last patient in this group was a primipara who had had inadequate prenatal care; when she arrived in the hospital, she was in convulsions and unconscious and died within a few hours.

In the cases referred to above, prenatal care was either absent or inadequate. To prevent such fatalities, patients must be taught to visit some physician regularly, and physicians must learn to see their patients regularly and attach more importance than these records show to increased blood pressure and albumin during pregnancy.

*Delivered cases.* Seventeen patients died after being delivered.

One of these had definite convulsions associated with a separated placenta; she was delivered by the Dublin method but died a few hours later.

Another patient went into labor spontaneously, and was delivered of a child by low forceps but died of eclampsia a few hours later. This patient had grossly inadequate prenatal care.

The next patient had been hospitalized for several weeks and died of a toxemia six hours after a normal delivery.

One patient developed eclampsia after a normal delivery and died two days later.

Another patient was seen frequently by her physician but was not sent into the hospital until convulsions appeared. The blood pressure was 220 systolic, 140 diastolic. She went into labor spontaneously and delivered a stillborn infant. She died five and a half hours after delivery. Although this patient had been frequently seen and apparently intelligently treated, the seriousness of the condition should have suggested the induction of labor much earlier. Had this been done, she probably would not have died.

The next patient, shortly after delivery, had what appeared to be convulsions and a cerebral hemorrhage, from which she did not recover.

One patient, who had been seen routinely during pregnancy and had been treated for syphilis, died eleven hours after delivery, apparently from circulatory collapse. She had had a systolic blood pressure between 150 and 160 and a good deal of albumin in the urine.

Another patient with increased blood pressure and albumin suffered separation of the placenta and died of anuria nine days after delivery.

The next patient was admitted to the hospital in labor. The blood pressure was 180 systolic, 100 diastolic. Following the first convulsion, she was delivered by version, even though the cervix was not fully dilated. The convulsions continued, and death occurred the same day.

One patient was said to have had a fulminating eclampsia. She delivered herself spontaneously and was doing well until three days following delivery, when she suddenly died, presumably of cerebral hemorrhage.

Another patient developed convulsions during

labor. The blood pressure was 176 systolic, 120 diastolic. Five more convulsions developed during the next twelve hours, and death occurred twenty-four and a half hours later.

The next patient, who had a blood pressure of 150 systolic, 130 diastolic, delivered herself of a macerated six months' fetus and presumably was doing well until a week later, when she developed a cerebral hemorrhage and died.

One patient was delivered by low forceps after a normal labor. She had previously shown increased blood pressure and albumin. She was brought into the hospital in coma, after having had a convulsion. There were five convulsions in all, and the patient died shortly after entry.

Another patient developed convulsions before delivery, and died shortly after the birth of twins.

The next patient, who had had excellent care during pregnancy, developed symptoms a week after the blood pressure and urine were normal. She had a separation of the placenta and died of a cerebral hemorrhage.

One patient, who had not been seen at all during pregnancy, had convulsions and did well so far as the toxemia itself was concerned, but died eighteen days later of a complicating pneumonia.

Two cases of toxemia were associated with cesarean section. One patient appeared in the hospital with convulsions. An emergency cesarean section was done, and she died of anuria three days later. An attempt to induce labor by rupturing the membranes was reported in the second case. This was not satisfactory, and since the patient was rapidly failing and labor had not started, a classic cesarean section was done, and she died the following day.

The most striking thing about this series is the number of patients who died of cerebral hemorrhage. There are three cases in which operative treatment can be criticized. The first is that of the patient who was delivered by version before full dilatation. It is believed that if labor does occur, the patient should be left alone until full dilatation, and that she should be allowed to deliver herself if the second stage is not prolonged. The other two are those in which cesarean section was performed. In cases of definite eclampsia, it is agreed that conservative treatment gives far better results.

#### TRANSFUSION

In 1940, 8 deaths were directly attributed to transfusion. One patient had been delivered by low forceps after a moderately rapid labor, and suffered a moderate post-partum hemorrhage. Transfusion was followed by a reaction within twenty minutes, which was evidenced by a severe

chill, an elevation of the pulse rate and lowered blood pressure. The donor and recipient were both in Group IV.

The next case in which incompatible transfusion was the result of death occurred in a woman who had had a severe post-partum hemorrhage associated with an inverted uterus. She had eight blood transfusions, and ultimately died of anuria.

One case occurred in a multipara who had a normal labor when about seven months pregnant and spontaneous delivery of a macerated fetus. She was brought to the hospital a few days later because of secondary anemia and a moderate degree of puerperal sepsis. A transfusion of citrated blood was immediately given, the bloods being typed and cross matched. Anuria and generalized edema set in, and death occurred twelve days later.

Another case was associated with an operation for rupture in a tubal pregnancy. Transfusion was done following the operation, and suppression of urine immediately set in. The patient died of uremia fifteen days after operation.

The next patient was a primipara, who suffered moderate post-partum hemorrhage following a forceps delivery. On the following day, the hemoglobin was 45 per cent and the red cell count 2,410,000. Fifteen minutes after a transfusion of citrated blood was started, the patient became weak and complained of loss of vision. Death occurred an hour and a half later.

One case occurred in a patient suffering from mitral stenosis with decompensation. When she was about four months pregnant, therapeutic abortion was performed. Because of hemorrhage, citrated blood from a donor of the same blood group as the patient was started shortly after the operation, but because of cyanosis and a severe chill was stopped after a small amount had been introduced. On the following day, another transfusion with the same blood was completed; death occurred eight hours later.

The next patient who died as a result of transfusion was a primipara who had had a difficult operative delivery. Three hundred and fifty cubic centimeters of blood from a donor of the same group, after direct matching, was administered. The patient became anuric and died forty-eight hours later.

The last case was associated with a transfusion following a cesarean section. Shortly after the transfusion was started, the patient had a severe reaction, and a complete suppression of urine followed. Death occurred two days later.

Although some of these deaths may have involved the Rh factor,—a circumstance whose sig-

nificance is becoming more generally recognized and appreciated,—the fatal outcomes in the majority of cases are inexcusable and clearly point out the need for more carefully and accurately performed compatibility tests.

#### PERNICIOUS VOMITING

Two patients died as a result of vomiting of pregnancy. One was approximately four months pregnant when pregnancy was interrupted by the introduction of a catheter, in addition to cervical packing. This patient entered the hospital with a temperature of 101°F., and died four days after admission to the hospital.

The other patient, who was sent into the hospital when about three months pregnant, had been vomiting continuously for eight weeks. She was aborted, but death followed.

Both these patients were treated conservatively too long before interference. Modern treatment—consisting of early hospitalization, intravenous therapy and intramuscular thiamin chloride—is so successful that therapeutic abortion is seldom necessary.

#### MESENTERIC THROMBOSIS

Mesenteric thrombosis was the cause of death in 2 cases. In one of these, the initial abdominal pain came on three hours after normal delivery. Laparotomy was performed thirteen hours later, when the diagnosis of mesenteric thrombosis was confirmed. The patient died forty hours after operation.

The other case of mesenteric thrombosis followed cesarean section. The acute symptoms appeared four days after the patient had been operated on. The patient died twenty-four hours later. The diagnosis was confirmed by autopsy.

These cases are extremely interesting and, fortunately, very unusual.

#### SEPSIS

A more careful review of the deaths in 1940 resulted in the classification of another case in which death was associated with sepsis. This patient had a diaphragmatic hernia; when she was about three months pregnant, it was decided, after medical and surgical consultations, that the hernia would make it unsafe for pregnancy to continue; hence, abortion was advised. No obstetrician saw this patient. An autopsy showed that the patient died of sepsis. The bacteriologic diagnosis was "gas bacillus, hemolytic type."

#### SURGICAL SHOCK

In 1 case, which is still under investigation by a medical examiner, death apparently resulted

from surgical shock following a ruptured bladder. The patient was found dead in an apartment house.

#### TREASURER'S NOTICE

The *New England Journal of Medicine* is sent to all fellows whose dues are fully paid. After March 1, names of delinquent fellows are dropped from the mailing list. All fellows are urged therefore to send, before March 1, their dues for the current year to their district treasurers.

CHARLES S. BUTLER, M.D., *Treasurer*

#### DEATHS

BRAGG—FRANCIS A. BRAGG, M.D., of Foxboro, died February 6. He was in his seventy-eighth year.

Born in Shutesbury, Dr. Bragg received his degree from Harvard Medical School in 1894. He was medical examiner for the Sixth Norfolk District and was a member of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, a daughter and two sons.

LOURIE—OSIP R. LOURIE, M.D., of Boston, died recently. He was in his sixty-ninth year.

Born in Russia, Dr. Lourie received his degree from the University of St. Vladimira Faculty of Medicine, Kiev, in 1896. He came to the United States in 1922, and practiced in Boston until his death. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

His widow survives him.

TEN BROECK—STANTON J. TEN BROECK, M.D., of Orange, died January 14. He was in his seventy-first year.

Born in Hillsdale, New York, Dr. Ten Broeck received his degree from New York University Medical College in 1893. He was a member of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, a son, three grandchildren and a sister.

#### WAR ACTIVITIES

##### UNITED STATES NAVY

The following medical officers of the United States Naval Reserves of the First Naval District have been assigned to active duty outside the First Naval District:

Allen, E. C., Lieut. (JG)

Bean, H. C., Comdr.

Belcher, C. D., Lieut. (JG)

Benson, H. L., Lieut. (JG)

Bigelow, R. B., Lieut. Comdr.

Bird, L. C., Lieut.

Boguniechi, S. J., Lieut. (JG)

Bronstein, B. R., Lieut. (JG)

Carlton, W. T., Lieut. (JG)

Carmody, R. F., Lieut. (JG)

Chamberlain, J. W., Lieut.

Cheever, F. S., Lieut. (JG)

Chesbro, W. L., Lieut.

Cone, T E, Jr, Lieut (JG)  
 Cruickshank, F S, Lieut. Comdr  
 Cummings, G E, Lieut (JG)  
 Farnsworth, D L, Lieut  
 Farrington, R F, Lieut. (JG)  
 Feldman, N N, Lieut (JG)  
 Fitzpatrick, W J, Jr, Lieut (JG)  
 Fleischer, H W, Lieut (JG)  
 Forbes, W W, Lieut (JG)  
 Fothergill, L D, Lieut Comdr  
 Fregosi, H J, Lieut.

Garrey, W E, Lieut  
 Gauld, A G, Lieut  
 Giuffrida, F, Lieut (JG)  
 Glazer, L, Lieut.  
 Gleason, R S, Lieut  
 Glickman, A M, Lieut  
 Goldblatt, H W, Lieut (JG)

Haddad, A K, Lieut (JG)  
 Halbach, R M, Lieut Comdr  
 Haslam, E T, Lieut (JG)  
 Hayes, J J, Lieut (JG)  
 Helgeson, U H, Lieut Comdr  
 Herrick, C A, Lieut (JG)  
 Higgins, R F, Lieut (JG)  
 Hinman, H E, Lieut (JG)

 Smith, E L, Lieut. (JG)  
 Smith, K E, Lieut. (JG)  
 Sommer, F X, Lieut (JG)  
 Stanbury, J B, Lieut (JG)  
 Stephens, H F, Lieut. (JG)

Tenney, B J, Lieut Comdr  
 Truslow, J B, Lieut. (JG)  
 Young, V T, Lieut (JG)  
 Zupanic, R, Lieut (JG)

## MISCELLANY

### NOTES

Sixteen appointments to the teaching and research staffs of the Harvard Medical School, the Dental School and the new School of Dental Medicine, effective during the present academic year, were recently announced as follows

*Medical School* Edward B D Neuhauser, of Cambridge, M.D., University of Pennsylvania '34, instructor in roentgenology, Vincent J Kelley, of Newton, M.D., Tufts, '25, assistant in laryngology, Sydney Ellis, of Boston Ph.D., Boston University '41, research fellow in pharmacology, James T Heyl, of Philadelphia, M.D., Harvard '37, research fellow in medicine John A Degen, Jr, of Chestnut Hill, M.P.H., Johns Hopkins '41, assistant in preventive medicine and epidemiology, Frederic W Rhineland, II, of Meadowbrook, Pennsylvania, M.D., Harvard '34, assistant in orthopedic surgery, Sam T Gibson, of Atlanta, Georgia, M.D., Emory University '40, research fellow in medicine, Earl H Wood, of Philadelphia, Ph.D., University of Minnesota '40, instructor in pharmacology, Gordon J Axelson, of Chicago, M.D., Duke University '37, assistant in medicine, Donald P Ham, of Mattapan, M.D., Boston University '38, assistant in roentgenology, Magnus I Smedal, of Waban, M.D., Harvard '29, assistant in roentgenology, William H Watters, of Boston M.D., Boston University '01, instructor in legal medicine, and Victor G Balboni, of Boston, M.D., Harvard '39, research fellow in medicine

*Dental School* Leonard N Donsanto, of Brighton, D.M.D., Harvard '38, assistant in oral surgery, and Wallace J Gardner, of Cambridge, D.M.D., Harvard '39, assistant in roentgenology

*School of Dental Medicine* John W Cooke, of Boston, D.M.D., Harvard '18, lecturer on clinical dentistry

The Trustees of Middlesex University announce that at a meeting held on February 9 they appointed Dr Stephen Rushmore as dean of the School of Medicine to take office on February 11, 1942

### ANNUAL MORTALITY SUMMARY FOR 1941

The number of deaths in eighty-eight major cities in the United States during 1941 decreased 0.4 per cent as compared with the 1940 figure for the same group of cities on the basis of provisional reports. There were 443,782 deaths reported in 1941 as compared with 445,504 deaths for the corresponding group of cities in 1940.

Except for three periods during the year, the weekly death rates for the major cities in the United States in 1941 were generally below those for the average death rates for the three year period, 1938-1940, inclusive. The first peak in the weekly mortality rates, which occurred in January and February, corresponded with the period of the influenza epidemic (see cut). Two conspicuous in

creases in mortality rates, in the latter part of June and in early August, were closely related to the heat waves that occurred over a large portion of the country.

The 28,166 infant deaths reported for 1941 represent an increase of 1319, or 4.9 per cent, over the 26,847 infant

represents a decrease of 8.9 per cent as compared with the final mortality rate of 40.5 for 1940.

In the comparison of death rates, it should be noted that the rates are based on the population as enumerated in the 1940 census. Inasmuch as there has been an unusual

### DEATH RATE BY WEEKS IN MAJOR CITIES

[RATE BASED ON 1940 ENUMERATED POPULATION]

deaths reported for 1940. However, on the basis of the provisional figures, the infant death rate for 1941 was 36.9 infant deaths per 1000 estimated live births, which

amount of population movement since the population census was taken, the rates for individual cities need to be interpreted with a certain degree of caution.

### BOOK REVIEWS

*Clinical Immunology, Biotherapy and Chemotherapy in the Diagnosis, Prevention and Treatment of Disease.* By John A. Kolmer, M.D., and Louis Tuft, M.D. 8°, cloth, 941 pp., with 27 illustrations, including 11 color plates. Philadelphia: W. B. Saunders Company, 1941. \$10.00.

This large and comprehensive volume suffers from the defects common to all textbooks that attempt to cover a vast and rapidly changing field. It is written by two distinguished authorities for the benefit of students and practitioners, and contains a mass of useful, practical information on the technic of performing tests within the scope of ordinary medical practice. There is probably no other book in which such a variety of practical data on the diagnosis, treatment and prevention of every sort of infectious disease is assembled. Because of its all-inclusiveness, the book is spotty. Too much space is devoted to many time-honored methods of treatment that are of dubious value, such as nonspecific protein and vaccine therapy. There are some glaring omissions, such as failure to discuss fever therapy in the section on gonococcal infections. But all in all, this volume represents a conscientious attempt to present to the practicing physician the theoretical and technical knowledge that is essential to the understanding and treatment of infectious disease. Such a book serves a useful function when the biologic and chemotherapeutic armamentarium is so extensive. The work is very much up to date, but in places a more critical appraisal of very recent methods of treatment would be better.

Although this book will not replace a consultant when the life of a patient is at stake, practitioners will find it

an extremely useful guide in the handling of patients with all sorts of infectious and allergic conditions.

*Medical Diagnosis and Symptomatology.* By Samuel A. Loewenberg, M.D. Fifth edition, entirely revised and reset. 4°, cloth, 1139 pp., with 520 illustrations. Philadelphia: F. A. Davis Company, 1941. \$12.00.

In the review of the first edition of this book (*New Eng. J. Med.* 201:199, 1929), attention was called to the fact that the book represented an expansive effort to encompass the field of physical diagnosis and clinical and laboratory medicine within the confines of an ordinary textbook. Although the format and arrangement have been modified, the scope of the book is unchanged. In the opinion of the reviewer, the net result can be summarized as a fair textbook of physical diagnosis that is grossly inadequate in all other respects. The symptoms of lobar pneumonia are described in about eighty words, and those of pulmonary tuberculosis in thirty-six words; and throughout the book, such superficial and sketchy descriptions abound.

Despite the fact that it has now reached the fifth edition, many errors of omission and commission are still noted. Thus, hyperthyroidism is not included in the differential diagnosis of mitral stenosis, and the sharpness of the first heart sound in hyperthyroidism is not mentioned. In describing the duration of the organic murmur, the author states that it "occupies nearly the whole of the systole, diastole or presystole." Under exophthalmos, the pulsating type is omitted. Space does not permit mention of a number of others. What might have been a good textbook of physical diagnosis appears, to the reviewer, to be less than a mediocre book on medicine.

## NOTICES

## ANNOUNCEMENT

DR HUGO B C RIEMER announces the removal of his Boston office from 128 Newbury Street to 29 Commonwealth Avenue

BOSTON DOCTORS  
SYMPHONY ORCHESTRA

The Boston Doctors' Symphony Orchestra will rehearse, under Alexander Thiede, every Thursday at 8 30 p.m. at Station WMEX, 70 Brookline Avenue, Boston. Those interested in becoming members should communicate with Dr Julius Loman, 520 Beacon Street, Boston (KEN 3200 or LON 2155)

Communicate with Dr Julius Loman, 520 Beacon Street, Boston (KEN 3200 or LON 2155)

## HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held in the amphitheater of the Peter Bent Brigham Hospital on Tuesday, February 17, at 8 15 p.m.

## PROGRAM

## Clinical presentation

The Pathology of Peripheral Neuritis Dr Derek Denny Brown

Physicians and medical students are cordially invited to attend

## BOSTON LYING IN HOSPITAL

A meeting of the Journal Club of the Boston Lying in Hospital will be held at the hospital on Wednesday, February 18, at 8 15 p.m. Dr Frank Barton, of the Massachusetts Memorial Hospitals, will speak on 'The Blood Bank and the Emergency'

Physicians and medical students are cordially invited to attend

## BOSTON SOCIETY OF BIOLOGISTS

A meeting of the Boston Society of Biologists will be held in the Eastman Lecture Room (G-120), Massachusetts Institute of Technology, on Wednesday, February 25, at 8 p.m.

## PROGRAM

Serum and Tissue Phosphatase in Experimental Scurvy Drs B S Gould and H Schwachman

The Biological Action of Short Waves A method for the determination of the local distribution and dosage Dr K. S. Lion

X-ray Diffraction and Electron Microscope Studies of Collagen Fibers Dr R S Bear, Mr C E Hall, Miss M A Jakus and Professor F O Schmitt

After the meeting, there will be a demonstration of the electron microscope and other biophysical apparatus in the Biological Laboratories

## BOSTON MEDICAL HISTORY CLUB

The Boston Medical History Club will hold its fourth meeting of the season at the Boston Medical Library on Wednesday, February 18, at 8 15 p.m. Dr John Romano

will speak on 'Early Contributions to the Study of Delirium Tremens'

All interested persons are cordially invited to attend

## MASSACHUSETTS MEMORIAL HOSPITALS

A staff meeting of the Massachusetts Memorial Hospitals will be held in the Evans Memorial Auditorium on Friday, February 27, at 8 15 p.m.

## PROGRAM

Report on the Laboratory Department Dr Charles F Branch

Carcinogenesis as a Conditioned Deficiency Dr Cornelius P Rhoads, director of the Memorial Hospital for Cancer and Allied Diseases, New York City

## JEWISH MEMORIAL HOSPITAL

A diagnostic and therapeutic conference will be held at the Jewish Memorial Hospital on Thursday, February 19, at 11 a.m. Dr Joseph C Aub will speak on 'Endocrine Problems'

Physicians and medical students are cordially invited to attend

## WALTHAM MEDICAL MEETING

The regular clinicopathological staff conference of the Metropolitan State Hospital will be held at the hospital on Wednesday, February 18, at 8 p.m. Drs Clementine McKeon and Richard C Wadsworth will present, 'Two Cases of Carcinoma, with Metastases to the Vertebra, Causing Great Pressure and Neurological Complications'. Dr Walter Wegner will lead the discussion.

All interested physicians are cordially invited to attend

## NEW ENGLAND PATHOLOGICAL SOCIETY

There will be a meeting of the New England Pathological Society at the Pathology Amphitheater of the Massachusetts General Hospital on Thursday, February 19, at 8 00 p.m. The exhibit room will be open at 7 30 p.m.

## PROGRAM

Exhibit of Pulmonary Surgical Specimens Drs R Klopstock, E D Churchill and Benjamin Casleman

Subdural Abscess A clinicopathologic study Drs C S Kubik and R D Adams

Isolation of Pleuropneumonia Like Organisms from Human Patients Drs W E Smith and L Dienes

The Nature of Pleuropneumonia Like Organisms Dr L Dienes

Renal Biopsies from Hypertensive Patients Dr Benjamin Castleman

Business meeting

Collation

## NEW ENGLAND HEART ASSOCIATION

A meeting of the New England Heart Association will be held in the Evans Memorial on Wednesday, February 25, at 8 15 p.m. It should be noted that the date has been changed from that originally announced

## PROGRAM

Effect of Venous Obstruction on Blood Flow in the Limbs Drs C K Friedland and R W Wilkins

Congenital Mitral Stenosis and Atresia Dr A S Nadus

Blood and Cell-Volume Determinations with Radioactively Tagged Erythrocytes. Drs. J. F. Ross and M. A. Chapin.

Ultimate Effect of Pregnancy on Rheumatic Heart Disease. Dr. N. H. Boyer.

Some Remarks Concerning the Clinical Diagnosis of Pulmonary Embolism and Infarction. Dr. Chester S. Keefer.

Interested physicians and medical students are cordially invited to attend.

#### NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

A regular meeting of the New England Society of Physical Medicine will be held at the Hotel Kenmore, Boston, on Wednesday, February 18, at 8 p.m. Dr. John H. Talbott will speak on "Physiologic and Therapeutic Effects of Hypothermia." Dr. Augustus Rose will lead the discussion. A council meeting will be held at 6 p.m., followed by an informal dinner in the Empire Room at 6:30.

All interested physicians are cordially invited to attend the meeting.

#### HEMATOLOGY JOURNAL CLUB

There will be a meeting of the Hematology Journal Club at the Joseph H. Pratt Diagnostic Hospital, Thursday, February 26, at 8:15 p.m.

##### PROGRAM

Discussion of cases.

Discussion of sickle-cell anemia.

Physicians and medical students are cordially invited to attend.

#### AMERICAN CONGRESS ON OBSTETRICS AND GYNECOLOGY

The second American Congress on Obstetrics and Gynecology will be held in St. Louis, Missouri, April 6 to 10, 1942. All the meetings and the commercial, educational and scientific exhibits will be held in the Public Auditorium.

The general plan for the program will be much the same as that of the first congress, which was held in Cleveland in 1939, with sectional meetings for the various groups (nurses, public-health officers, administrators, educators and physicians), general sessions for all members attending the congress and round-table discussions. The evening sessions will be open to the general public.

Admission to the congress will be by membership cards only, which may now be secured by the payment of a \$5.00 registration fee. All mail should be addressed to and further information may be obtained from the American Congress on Obstetrics and Gynecology, 650 Rush Street, Chicago.

#### UNITED STATES CIVIL SERVICE EXAMINATION

##### Orthopedic Mechanics

An examination has been announced by the Civil Service Commission to secure orthopedic mechanics for the Army services. The salary is \$2000 a year. Persons may qualify under the following optional subjects: General, bracemaker, shoemaker and leatherworker, and limb-maker. Because of the demand for qualified eligibles,

applications will be accepted at the Commission's Washington office until further public notice.

Persons appointed will construct, design, alter and repair orthopedic appliances as indicated by the optional subjects. This includes working from living models and plaster casts, doing nickel plating, and shaping, grinding, and polishing metals used in orthopedic appliances.

Applicants will not take a written test, but will be rated on the extent and quality of their experience. They must have had five years of appropriate experience in orthopedic work within the past ten years. Under the option "shoemaker and leatherworker," persons whose experience has been in general shoe repair will not be considered qualified.

Examination announcements and application forms may be obtained at first-class and second-class post offices and from the Civil Service Commission, Washington, D. C.

#### SOCIETY MEETINGS AND CONFERENCES

##### CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, FEBRUARY 15

###### MONDAY, FEBRUARY 16

12 15-1 15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital amphitheater.

###### TUESDAY, FEBRUARY 17

\*9 00-10 00 a.m. Medical clinic. Dr. S. J. Thannhauser Joseph H. Pratt Diagnostic Hospital

\*12 00 m. Chemotherapy. Dr. Maxwell Finland South End Medical Club Headquarters of the Boston Tuberculosis Association 571 Columbus Avenue, Boston.

12 15-1 15 p.m. Clinicoroentgenologic conference. Peter Bent Brigham Hospital amphitheater.

8 15 p.m. Pathology of Peripheral Neuritis Dr. Derek Denys Brimley Harvard Medical Society, Peter Bent Brigham Hospital amphitheater.

###### WEDNESDAY, FEBRUARY 18

\*9 00-10 00 a.m. Recent Advances in Allergy Dr. E. A. Cowdrey Joseph H. Pratt Diagnostic Hospital.

\*12 00 m. Clinicopathological conference. Children's Hospital

12 00 m. The X ray in Diseases of the Digestive Tract and Biliary System. Dr. Samuel A. Robins and his associates Boston Gastroenterological Society, Beth Israel Hospital.

\*8 00 p.m. Physiologic and Therapeutic Effects of Hypothermia Dr. John H. Talbott. New England Society of Physical Medicine Hotel Kenmore, Boston.

\*8 15 p.m. Early Contributions to the Study of Delirium Tremens Dr. John Romano. Boston Medical History Club, Boston Medical Library.

\*8 15 p.m. The Blood Bank and the Emergency Dr. Frank E. Boston Lying-in Hospital.

\*8 30 p.m. The Use of Drugs in the Treatment of Alcoholism Dr. Wilfred Bloomberg. Washingtonian Hospital.

###### THURSDAY, FEBRUARY 19

\*9 00-10 00 a.m. Medical clinic. Dr. S. J. Thannhauser Joseph H. Pratt Diagnostic Hospital.

\*11 00 a.m. Endocrine Problems Dr. Joseph C. Aub Jewish Memorial Hospital.

8 00 p.m. New England Pathological Society. Massachusetts General Hospital.

###### FRIDAY, FEBRUARY 20

\*9 00-10 00 a.m. Clinical and Experimental Observations on the Use of Thyrothricin in the Treatment of Infections Dr. C. H. Kamp. Joseph H. Pratt Diagnostic Hospital.

###### SATURDAY, FEBRUARY 21

\*9 00-10 00 a.m. Sulfur Metabolism Dr. Martin Nothmann Joseph H. Pratt Diagnostic Hospital

\*Open to the medical profession.

NUMBER 8

## RECURRENT PYELONEPHRITIS DURING PREGNANCY\*

GEORGE C. PRATHER, M.D.,† AND WESTON SEWALL, M.D.‡

BOSTON

**A**FTER completion of a pregnancy during which pyelonephritis has been a complication, both the patient and her physician are interested in the question, Will there be a recurrence of recurrence, as well as the factors that may influence a recurrence, are the purpose of this paper, the data were derived from the records of 72 patients with pyelonephritis asso-

FIGURE 1

*This patient, a para II had a right pyelonephritis during the seventh month of pregnancy. A shows the pyelographic changes in the pelvis and ureter. B, taken three years later when the patient was again pregnant, shows nearly identical anatomic changes.*

rence of "pyelitis" if another pregnancy ensues? An answer, not necessarily correct for an individual, can be given on a statistical basis. The

\*From the Urological Department and Obstetrical Department, Boston Lying-in Hospital.

†This factor in general surgery, Harvard Medical School, assistant urologist, Boston Lying-in Hospital.

‡Assistant in obstetrics, Harvard Medical School, assistant obstetrician to outpatients, Boston Lying-in Hospital.

ciated with pregnancy who later returned to the hospital for one or more subsequent pregnancies.

During their first pyelonephritis of pregnancy, 70 of the 72 patients had pyelonephritis before delivery, in 2, the pyelonephritis occurred immediately afterward. Forty-three patients were in a febrile phase while in the hospital, and 29 were

admitted or seen following their febrile attack. Approximately 58 per cent were primiparas. A past history indicative of an inflammatory type of kidney disease was obtained in 17 per cent. Urinary studies demonstrated a bacillary type of infection in 91 per cent, gram-positive cocci in 5 per cent and mixed infection in 4 per cent. The clinical findings indicated involvement of the right kidney alone in 48 per cent, bilateral disease in 32 per cent and left renal infection alone in 20 per

cent developed pyelonephritis in subsequent pregnancies; the remainder — about 12 per cent — had toxemia in subsequent pregnancies. The 17 patients who developed recurrent pyelonephritis had a total of twenty-two pregnancies following the original one with pyelonephritis. The interval between pregnancies varied from one to five years, with an average of three years.

The importance of a cure of the urinary infection either during pregnancy or in the interval be

FIGURE 2.

*This patient, a primipara, had a right pyelonephritis during the sixth month of pregnancy. A shows the typical pyelographic changes in the upper urinary tracts. B, taken nine months later, shows considerable resolution of the hydronephrosis and hydrometer.*

cent. Cystoscopic diagnoses were made in 34 patients.

Studies of renal function were not done routinely at the time of the first observations. The blood chemical findings, which of course did not measure slight changes in renal function, were normal in 40 cases.

This brief summary of the clinical data involving the initial attack offers nothing new on the subject, but the following material, which shows the course of events when the patients returned in a subsequent pregnancy, is of interest. In approximately 65 per cent, the subsequent pregnancy was normal, with no clinical evidence of pyelonephritis. Seventeen patients, or 23 per cent, de-

tween pregnancies has been emphasized repeatedly.<sup>1,2</sup> Likewise, careful examination of a catheter specimen of urine by stained sediment or culture has been stressed as essential in determining cure. Data from this series of cases support both contentions. Of 43 patients in whom a sterile urine was obtained post partum following their initial pyelonephritis of pregnancy, 8, or 19 per cent, developed pyelonephritis in a subsequent pregnancy. Of 36 patients whose urine was either still infected or unreported during the interval between pregnancies, 14, or 42 per cent, developed pyelonephritis in a subsequent pregnancy. (The total of 79 patients, instead of 72, is conditioned by the fact that a few patients had both a subse-

quent normal pregnancy and one complicated by pyelonephritis.) If one assumes that at least some of the patients whose urine was unreported probably had a sterile urine between the interval of pregnancies, the rate of recurrence of pyelonephritis in women who begin their pregnancy with an infected urine would be even greater than the 42 per cent just quoted.

Thus, a woman who has had pyelonephritis associated with pregnancy appears to have about one chance in four or five of developing pyelonephritis during a later pregnancy. The likelihood that pyelonephritis will recur during a later pregnancy, however, is greatly increased if she enters the succeeding pregnancy with an infected urine. Entering pregnancy with a latent or chronic pyelonephritis, she has only one chance in two of avoiding a febrile attack; if the pyelonephritis has been cured during the interval between pregnancies, the chance of her having a febrile attack is reduced to less than one in five.

Pyelographic data were obtained in 55 patients, in 29 of whom cystoscopy and retrograde pyelography were performed. Intravenous pyelography was used in the remaining 26. Two illustrations of the pyelographic studies are instructive. Figure 1 illustrates delayed secretion of the intravenous dye by the right kidney during two pregnancies three years apart, each of which was complicated by right pyelonephritis. It is interesting to observe the same degree of ureteral dilatation in the two pregnancies even though the position of the fetal spine is reversed. Figure 2 illustrates the degree of anatomic recovery that may take place following pregnancy.

To demonstrate the relation of hypertension to pyelonephritis, we have noted the blood pressure readings from the charts of 17 patients who had recurrent pyelonephritis (Table 1). Although the

average interval between pregnancies was not unusually long, there appears to be no tendency toward hypertension during a succeeding pregnancy

37	1934	150/88	1938	128/80

as the result of pyelonephritis during a former pregnancy.

#### SUMMARY

In a series of 72 patients, recurrent pyelonephritis of pregnancy had an incidence of 23 per cent. If the urine becomes sterile during the interval between pregnancies, the chance of recurrent pyelonephritis is less than one in five, and if the urine remains infected, the chance is about one in two.

There appears to be no tendency toward hypertension during a succeeding pregnancy as the result of pyelonephritis during a previous pregnancy.

## THE GOVERNOR'S ADDRESS\*

ROBERT O. BLOOD, M.D.

CONCORD, NEW HAMPSHIRE

**T**HE participation of the state in the practice of medicine, from both the physician's and the state's point of view, extends over the last hundred and fifty years. I propose to deal with the incidents and developments that have shaped our present-day state health program, the relation between the state medical profession and expanding government control, and subsidy of state health.

The New Hampshire Medical Society is closely associated with early efforts to promote state responsibility for common health conditions. Following its incorporation by the legislature in 1791, the Society promoted standards for physicians, an action that shows clearly its concern for public health and welfare. Numerous later acts of the Society indicate its concern with the public at large. In this respect, and proudly, it was the forerunner of an organized public-health agency. Sensitive to its responsibility to New Hampshire citizens, the Society adopted the following two resolutions in 1824:

RESOLVED, That the practice of depositing medicines in stores, taverns and grog-shops, with directions to the common people for their use, is not only pernicious to the health and morals of society, but derogatory to the character and reputation of the physicians.

RESOLVED, That we disapprove the encouragement held out to the public through the medium of pompous advertisements, that the daily use of bitters is conducive to health; and we consider the facility with which Stoughton's Elix. Spec., bitters etc. may be secured at country stores, one of the most direct means of inducing habits of intemperance (the bane of society) of any within our knowledge.

Early in the nineteenth century, the Society attempted to establish a medical school in Concord, hoping to elevate the standards of professional public-health guardians. The Society's bitter struggle to protect the community from the inducements of the infamous Concord Botanic Infirmary is another indication that it was not passive in armoring the community against the invasion of a medical hoax.

The Society agitated early for control of vital statistics by the State. In 1848, it appointed a committee to study the problems relating to birth and death registration, and to bring the issue before the legislature.

In 1868, Dr. Granville P. Conn, a man whom I knew as an able physician and energetic leader in the early field of public health, joined the committee of the Society. Not at once successful in putting through state legislation, he cut through the jungle of indifference, ignorance and tradition. Indirectly prodding the State by initiating local ordinances, he finally succeeded with similar state legislation, but not for a decade.

The New Hampshire Medical Society entered the campaign for a state board of health largely as the result of an address delivered in 1872 by a Californian, Dr. Thomas M. Logan. Speaking as a realist, from experience gained in California's campaign for similar action, Dr. Logan outlined the duties of a state board of health as follows:

To create an interest in our work among the lay as well as the professional public. . . .

To raise up friends in all parts of the state to co-operate with us in our investigations in gathering sanitary information and in spreading it abroad. . . .

To encourage the formation of local boards of health, the registration of births, deaths and marriages, whereby mortality and other reports touching the vital condition of the people may be obtained.

Dr. Logan, like New Hampshire's Dr. Conn and others in the nation, was more than a diagnostician of bodily ills. He was an economist, a statesman and a prophet—all these, because he envisioned the broad economic and human influence of a sound program of state health regulation.

Dr. Conn, in the enthusiastic wake of Dr. Logan's appeal, was assigned to draft a bill for a state board of health and to secure its passage. Toward that end, he labored for a decade. He visited, he lectured, he taught, he influenced. For ten years, he carried on with prodigious energy, creating and sustaining interest in his public-health ideal. The records of the Society are marked during this period with efforts to create a state board of health. Since it is material available to all in the published reports of these years, I shall not deal with it. In the year prior to the passage of the act creating the board, the president of the Society wrote in his annual address:

A physician is often considered as a kind of fire extinguisher, to be sent for in time of conflagration, but as rather a useless member of the body politic when there is no actual crisis. To think this way is to wholly misunderstand the work of the professions. . . . The physician should have the same pre-

\*An address delivered by the Governor of New Hampshire at the one hundred and fiftieth Anniversary Dinner of the New Hampshire Medical Society, Manchester, May 14, 1941.

rogative in the state as in the family, and no man can be properly said to be a conscientious physician who does not, if allowed, have a general, vigilant, but not impertinent oversight of the hygienic arrangements of the household of which he is the sanitary inspector and adviser.

In 1881, the state legislature created a state board of health. Dr. Conn, exultant in his success, was at once appointed to the Board.

The Board of Health, under the terms of the act, was to consist of four appointees: three physicians and a civil engineer. It was granted license to elect its officers and to institute rules necessary to guard against epidemics or contagious disease, to be dispensed to citizens without cost. Cognizance was taken of sanitation in public buildings. Vital statistics were taken over by the Board. Local boards were to be assisted and advised; conditions in localities were to be investigated. That the people of the State should be served was pre-eminent in the writing of the act.

Examination of public-health legislation in New Hampshire is a study in itself. In 1892, all State Board of Health regulations were made enforceable by an act that made their violation punishable by fine. Also in 1899, the practice of embalming was brought under regulation, and thus the Board's authoritative arm stretched into a new orbit. In 1901, the Board was "authorized to establish and equip a laboratory . . . for the chemical and bacteriological examination of water supplies, milk, food products and drugs; and the investigation of cases and suspected cases of diphtheria, typhoid fever, tuberculosis, pneumonia, malaria glands and other infectious and contagious diseases." A chemist was to make investigations and analyses of public water supplies and of foods and drinks offered for sale in markets, to discover adulterated and fraudulent products. A quarterly bulletin was to be published. Moreover, all investigations by the Board were to be made free to the people of the State. In the same year, vital statistics were indexed by law. The following year, an act provided for the restriction of communicable diseases. The procedures familiar to all physicians today were made law: quarantine, case reporting to local and state boards of health, placarding of quarantine premises and disinfection of infected premises.

In 1903, the legislature passed an act to enable the State Board of Health to prevent the furnishing of contaminated water for domestic consumption, and in the same year gave the superior court jurisdiction in equity to enforce the orders of the Board. The session of 1907 was successful in pure-food legislation, with an act preventing the manufacture or sale of adulterated or misbranded

or poisonous foods, drugs, medicine and liquors. In this, the Board was to assume regulatory supervisory powers.

At the next session, the powers of the Board were further extended by an act providing for the establishment of dispensaries for the detection and treatment of tuberculosis. In the same year, supervisory power was given the State Board of Health over the manufacture and sale of cocaine products. Other legislation in 1909 provided for sanitary inspectors, embracing the examination of meats and general food products and of local sanitary conditions.

As an extension of the tuberculosis clinics and in an effort to check the spread of the disease, the Board was charged, in 1911, with the registration of all cases. The same year was also marked by its authority to enter and inspect establishments producing or selling food. With an act relating to child labor, the State Board of Health entered the province of public-welfare work, for the act authorized the regulation of child labor by the staff. Later, the Board assumed control of communicable diseases in unincorporated districts; thus, it acknowledged responsibility for the health of those in the rural areas of the State. For many years, members of the medical and nursing professions had campaigned for legislation to cover the care of inflammation of the eyes in the newborn—ophthalmia neonatorum. The Board was authorized to make regulations designed to prevent this disease. Furthermore, an act was passed to provide for certified and inspected milk.

During the next three sessions of the state legislature, medical inspection of schools was made compulsory, as was the formal reporting of occupational diseases. Regulations were made dealing with the discharge of sewage into streams, and providing for the construction and enlargement of public water systems. The control of the Board over infantile eye diseases was increased, and the distribution of antitoxins was provided for. The Board was also authorized to govern the sanitation of schoolhouses and to examine their teachers and janitors for communicable diseases, and power was given to license and inspect private asylums and sanitariums.

The trend during these first thirty-nine years is obvious. More than a trend, it is a lively and colorful pageant of human betterment. The demand for the services of the State Board of Health increased. Each session of the legislature witnessed the passing of additional laws, added health burdens being placed on the staff of the Board. It has been a consistent rise—even to the present day. This historical development of New Hamp-

shire's Board of Health led to the broad program in effect today.

Increased responsibility and added functions were accompanied, inevitably, by a mounting health budget. Always, leading to the battle front of progressive government, there must be a pipeline of monetary supply. It must be maintained; it must be guarded; and even more important, it must be regulated. That is the strategy of "good government." There is, however, an interesting balance between function and cost. This is evident regarding the activities of the Board of Health in New Hampshire.

Under the terms of the original statute of 1882, the total cost of the Board's operation was not to exceed \$3,000 in any year—a calculation that was both naïve and optimistic; it suggests the man who makes his "down payment" and walks away with the inflated pride of full ownership. Actually, the operation of the Board during the next year approached the \$5,000 mark, and by 1886, the total annual expenditure was well over \$8,000. The following years, up to the turn of the century, averaged between \$4,000 and \$7,000. In 1902, the year in which the Laboratory of Hygiene went into operation, the cost of the Board rose to more than \$14,500. This was a high level for the decade that followed. In 1913, because of the salaries of chemists, bacteriologists and sanitary inspectors and the cost of vital statistics, the budget expenditures increased to more than \$16,000. This level was maintained, more or less, until 1920, when the total expenditure of the board reached \$27,000. Five years later, this figure was shadowed by a total expenditure of more than \$70,000, a cost very nearly repeated in 1930.

The initial federal grant-in-aid for state health activities came in 1936, when the State availed itself of \$8,423. In the same year, the State contributed, in addition, \$73,671. From \$8,000 in 1936, federal money expended for health purposes rose in 1937 to \$52,000, and to more than \$83,000 in 1938. In the latter year, the state appropriation and expenditures exceeded this amount, bringing the cost of public-health functions in the State to more than \$167,000. The federal grant in 1939 rose to more than \$100,000; this was matched by state funds of \$95,000. In 1940, the last full year available, federal and state expenditures totaled almost \$205,000. These five years, 1936 through 1940, have witnessed a total expenditure of more than \$362,000 in federal funds, matched by \$410,000 in money contributed by the State, an aggregate expenditure on state public health of nearly \$772,000. Dr. Conn. who asked for a few hundred dollars for birth and death registration, would have been startled at these figures.

The annals of individual achievement are no more praiseworthy in any section of the country than in New Hampshire among the members of the medical profession, who toiled long and arduously for the gains we count today; moreover, they often toiled without adequate clinical and surgical equipment. They were men who generously subordinated their own comfort to communal welfare. They were familiar with the long journeys to hillside homes. Often, they were deprived of the nourishment of sleep when the wheel of rest was suddenly halted by a neighbor-messenger. In their time, they were the claim adjusters of human affairs, assuaging malice, greed and misunderstanding. They sat through the long nights to listen to the caricature of men's lives as it sifted through the veil of half-consciousness. In many respects the first citizens of the State, they were welcomed to the great aristocratic residences and hailed in the remote, silent reaches of the northern logging roads. With scant knowledge of many medical subjects now commonplace, they often resorted to desperate means in saving human life—and with incredible success. A stalwart lot, whose business was rooted deep in human behavior, they frequently applied the anesthetic of prudence when skill was lacking. They were the first proponents of collective and organized public health. For they were the itinerant teachers of elementary hygiene in the home. Whereas today a relatively complicated scheme operates, they once gave generously of their efforts, sometimes ushering in new life, six miles from home, for the "munificent fee of fifty cents." We have increased our mastery over time and space. We have organized our individual experience and resources in a state board of health. These are distinct advances, but in many respects, earlier men were the conquerors of problems more formidable than those of the present day.

New Hampshire is spending heavily on public-health projects. The burden of this to the taxpayer has a significance that cannot be discussed here. The increasingly heavy outlays are also, I am convinced, of vital consequence to physicians in the State. The medical profession is one of the few individual careers left. Increasing governmental participation will standardize the performance of professional men engaged in medical practice. Although the average level may be slightly raised, the medical "artist" will be reduced to uniform work. Increased subsidy means greater uniformity and the loss of the great men of medical science. That, briefly, is the case for the profession itself.

There is also a case for the people of the State, particularly the needy sick. If the sponsors of government-regulated medicine are earnest in their

endorsement of adequate medical care, they will see to it that such care is rendered by professionally competent men; it cannot be provided in any other way. The citizens should be cautious in estimating the ability of legislated medicine to provide competent medical care for the needy, just as careful as they should be in protecting themselves from the advice and treatment of nonmedical practitioners. There is grave doubt whether any body politic can properly assess the needs of the indigent sick. Such action must be left in the hands of the medical profession. The welfare of the sick will be best preserved by continuation of the traditional principle of allowing the patient to choose his physician. That right must be maintained, unless the patient is judged incapable of making the selection. The underlying value of this prerogative is well understood by the medical profession, although often regarded casually by governmental health, welfare and relief administrators.

What is the answer? Must we cease altogether to accept governmental aid in our health program? And, if we do, what is to become of the organization already in motion? I do not believe that we need ignore the aid offered our state units. To do this would be to renounce the obligation of delivering scientific medical care to the people, whether they can afford it or not. No one in the profession is tolerant of that attitude, and if he were, the profession would not long remain tolerant of him. The State Board of Health, like other welfare and relief agencies, must be main-

tained to meet the demands that education is prompting the people to make. We cannot educate the citizenry to better health and then withhold it from them. The solution rests, I am convinced, with the medical profession itself. A successful program must keep in mind three essential functions: preventive medicine, curative treatment and the care of those chronically ill.

\* \* \*

Thus, from the earliest times there has been a constant demand for increasing state participation in the regulatory controls of the State Board of Health. With this extended control has come a constant demand for ever increasing amounts of money to perform these functions, the State has met these demands. In general, the requests have come from the medical group and not from the layman. Of course, the money to pay these bills comes, in the final analysis, from the taxpayers. With the growing financial participation of governmental units has come increased control over the functions of public health. This privilege has been claimed on two arguments: that it is economical, and that the organization, or people furnishing the money, has a right to dictate its use. In these days, when the medical profession is rightly opposing state medicine and increased regulations of its practice, I believe that physicians should weigh carefully the advisability of asking for additional governmental participation, lest we receive, in its wake, the state regulation of the practice of medicine.

PERINEAL PHLEGMON\*

S. RICHARD MUELLNER, M.D.†

BOSTON

THIS paper is based on a study of 36 cases of perineal phlegmon treated at the Boston City Hospital during the last ten years.

Perineal phlegmon, or periurethral gangrene, is referred to as "extravasation of urine" in the older textbooks of urology. It was observation of cases of this disorder that led Colles<sup>1</sup> to the discovery of the superficial perineal fascia; he believed that extravasating urine was confined to the superficial perineal pouch by the anatomic attachments of the fascia, which he described in 1811. So-called "urinary extravasation," or perineal phlegmon, was at that time considered to be due to seepage of urine into the tissues through a tear in the urethra proximal to a stricture. One can readily understand the logic of this concept, since it stems from an era when little was known about bacteria or the chemistry of urine, and the identification of the fluid in the tissues depended entirely on the senses of sight and smell.

In recent years, this mechanistic view of the etiology of perineal phlegmon has been discarded by many. French urologists have claimed for years that perineal phlegmon is due to an infection by anaerobic bacteria.<sup>2</sup> Keyes and McLellan,<sup>3</sup> Herman<sup>4</sup> and Keyes and Ferguson<sup>5</sup> agree with this concept and assert that urine is never found in the tissues of the perineum, scrotum, penis and abdominal wall in cases of perineal phlegmon.

However, some writers on this subject still hold to the old view of urinary extravasation in spite of considerable evidence against such a belief.<sup>6-10</sup> Briefly, this evidence is as follows: lacerations of the urethra through which the seepage of urine might be expected to occur are rarely, if ever, demonstrable at operation; collections of fluid in the tissues have been seen to occur distal to a stricture of the urethra<sup>11</sup>; stricture of the urethra is often absent (Table 1); a comparison of the urea content of the fluid in the tissues and of the bladder urine shows that the former is definitely not urine<sup>5</sup>; and injection of sterile urine into the tissues of experimental animals has failed to reproduce the syndrome of perineal phlegmon.<sup>12, 13</sup>

\*Presented at a meeting of the New England Section of the American Urological Association, Boston, April 24, 1941.

†Instructor in urology, Tufts College Medical School; assistant visiting urologist, Boston City Hospital; junior visiting urologist, Beth Israel Hospital.

That the fluid in the tissues was definitely not urine, was easily proved in 3 of the 36 cases observed in this study. In these patients, the fluid in the subcutaneous tissues was watery, and contained aerobic and anaerobic bacteria, whereas the bladder urine was concentrated, clear and sterile.

A significant matter, which has not been stressed before, is the role of the lymphatic channels that drain the membranous and bulbous urethra, as well

TABLE 1. Incidences of Urethral Stricture and of Urinary Infection in Cases of Perineal Phlegmon.

CONDITION OF URETHRA		BLADDER URINE AT OPERATION	
	PERCENTAGE OF CASES		PERCENTAGE OF CASES
Small-caliber stricture (impassable) . . . . .	53	Infected . . . . .	59
Large-caliber stricture (passable to No. 16 to 20 Fr. catheter) . . . . .	22	Mildly infected (5 to 10 white blood cells per high-power field) . . . . .	11
Normal lumen . . . . .	25	Sterile . . . . .	39

as the perineum, scrotum, penis and lower abdominal wall. These lymphatics, interestingly enough, follow accurately the outlines of Colles's fascia.<sup>14-16</sup> Individual variation in the course of the lymphatics, moreover, is not uncommon, and such variations may well account for the surprising spread of the phlegmon beyond the confines of Colles's fascia. Thus, in 2 of the cases in this series, the infection extended to the thighs, and in 5, a great deal of fluid was found in the pre-vesical space at cystotomy. Extension of the inflammatory reaction to the axillas and buttocks has been recorded in the literature.<sup>2</sup>

The clinical picture of perineal phlegmon is briefly as follows. The onset of the infection is often marked by chills and fever, followed by pain and swelling of the perineum and accompanied by increasing difficulty in voiding. In some cases, a long history suggestive of stricture of the urethra precedes the onset of the illness. The perineal swelling quickly spreads to include the scrotum, penis and abdominal wall. On examination, the patient is feverish and toxic, even comatose. The pulse is rapid and weak. The bladder is readily felt suprapubically, the hypogastric area is swollen, the penis and scrotum are often enormous, and the perineum bulges extensively.

The diagnosis of perineal phlegmon is readily made on the basis of the history and physical

findings In the differential diagnosis, periurethral abscess or an ischioirectal abscess pointing in the perineum must be excluded The following cases illustrate some of the typical features of the condition

### CASE REPORTS

CASE 1 B M, a 49 year-old Negro, entered the hospital because of swelling of the penis and scrotum of 74 hours duration He had had gonorrhea 13 years before entry this had been treated by self-medication Since then symptoms suggestive of stricture of the urethra had been present On the day before admission the patient noticed soreness in the perineum, followed by a local swelling which rapidly extended to the scrotum and penis and was accompanied by retention of urine, fever and malaise

On examination the patient was feverish and in distress The bladder was palpable at the level of the umbilicus There was a swelling over the hypogastrium and the penis and scrotum were enormously swollen, red and edematous

At operation an impassable obstruction was found in the urethra 8 cm from the meatus Through a median perineal incision the subcutaneous tissues were found to be very edematous The edema fluid was colorless and of fecid odor, and the culture yielded a beta hemolytic streptococcus and *Staph aureus* The perineal incision was undermined and connected by rubber tissue, with counterincisions in the groins scrotum and penis The bulb and the urethra were explored and were found to be intact but very cyanotic, with engorged veins on their surfaces A perineal urethrotomy was performed A No 20 catheter passed easily into the bladder Clear urine-colored urine, which was later found to be sterile and pus free, was obtained from the bladder

The postoperative course was very satisfactory On the 26th day after operation the urethra was readily dilated with bougies and sounds The patient was discharged 5 weeks after admission the wounds were healed and he was able to void a good stream

CASE 2 W M, a 67 year old man, was admitted because of swelling of the genitalia and retention of urine Two weeks before entry the patient noticed swelling of the penis and scrotum, in addition to inability to void He had had gonorrhea many years previously, but had no symptoms of stricture of the urethra

On admission the patient was stuporous and very dehydrated The bladder was palpable below the umbilicus The suprapubic area was swollen, and the skin was red and blistered The penis and scrotum were enlarged to three times their normal size The perineum was bulging and red, and the inflammatory reaction extended over the buttocks

The operative procedure was essentially the same as that in Case 1, except that the bladder was drained by cystostomy The prevesical space was edematous The bladder contained concentrated sterile urine In the perineum, the subcutaneous tissues were gangrenous and bathed in foul pus, which on culture yielded an alpha hemolytic streptococcus, *Staph aureus* and an enterococcus The urethra and the bulb were intact, but the urethral mucous membrane consisted of gray slough, so that the urethral lumen was obliterated When an attempt was made to pass a bougie into the urethra, the instrument stuck in the meshes of the slough, which was of a gritty consistence Postoperatively, sulfathiazole was used as an adjunct to combat the infection

The convalescence was uneventful It was remarkable that the urethral lumen became reestablished at the time of the patient's discharge from the hospital

CASE 3 J M, a 51 year-old man, was extremely toxic and comatose at the time of entry He was said to have had swelling of the genitalia and difficulty in voiding for the previous 2 weeks

The temperature was 104°F, and the pulse 120 weak and thready The bladder was not palpable The hypogastrium was swollen, red and blistered, and red streaks extended to the upper abdomen and over the thighs The genitalia were greatly swollen the perineum bulged, and the buttocks were red, blistered and indurated

The operative procedure was the same as that in Cases 1 and 2 The subcutaneous tissues were edematous and sloughing On culture an alpha hemolytic streptococcus and a fusiform bacillus were found The urethra and the bulb were intact, but the urethral mucous membrane was black and sloughing obliterating the urethral lumen, in a manner similar to that in Case 2 The bladder contained about 180 cc of uninfected, concentrated urine

Postoperatively, and without regaining consciousness, the patient developed signs of bronchopneumonia and died days later

### DISCUSSION

These case reports bring out a few points that merit emphasis Colles's fascia was no barrier to the spread of the pathologic process Moreover, the urine in each case was concentrated and sterile, yet the fluid in the subcutaneous tissues was watery

TABLE 2 Analysis of Cases of Perineal Phlegmon, Showing Mortality Morbidity and Age Distribution

Mortality	3 per cent
Morbidity	
Average 1 hosp al stay	44 days
Longest hosp stay	94 days
Shortest hosp al stay	12 days
Age	
Average	55 years
Oldest	7 years
Youngest	26 years

and foul and harbored various aerobic and an aerobic bacteria Laceration of the urethra was not demonstrable Finally, the urethral mucous membrane in Cases 2 and 3 was gangrenous and sloughing, and thus produced an obliterated lumen The passage of an instrument through such a urethra could easily give the erroneous impression that a stricture existed

The prognosis of perineal phlegmon is grave The morbidity is high, and the mortality has remained at about 40 per cent (Table 2)<sup>1</sup> The high mortality is partly due to the age and the debility of the patient with this lesion, and partly to the high virulence of the infection in certain patients Although delay in making a diagnosis and beginning treatment obviously adds to the seriousness of the outcome, prompt action does not always prevent death (Table 3) Of 11 patients in the same age group, who were treated

in a similar manner during the first three days of the disease, 6 survived and 5 died.

The management of perineal phlegmon is based on three principles: treatment of the infection; relief of the retention of urine; and treatment of the urethral stricture.

Prompt and adequate surgical drainage, with thorough decompression of the distended tissues, is the paramount factor. This can be accomplished by long, free incisions, or by multiple

TABLE 3. *Relation between Preoperative Duration of Perineal Phlegmon and Postoperative Mortality.*

DURATION OF ILLNESS <i>days</i>	NO. OF SURVIVALS	NO. OF DEATHS
1-2	6	5
3-6	7	2
7-14	3	2

incisions, widely undermined, and connected by rubber tissue. I prefer the latter method, because, if it is properly executed, satisfactory drainage and decompression result and healing is more rapid, with less scarring and deformity.

Chemotherapy, based on accurate bacteriologic and renal-function studies, is a valuable therapeutic adjunct. Zinc peroxide dressings, the local application of sulfanilamide powder and irrigation of the wounds with Dakin's solution are also useful.

The retention of urine is best relieved by cystotomy, particularly if dense strictures of the urethra are present or if the urethral mucous membrane is gangrenous and sloughing. It is amazing how rapidly such a urethra regenerates if it is not unduly traumatized. Bladder drainage may be established by perineal urethrotomy if the urethra is strictured and no slough is present or by penile catheter if the urethra is intact. The stricture of the urethra can be dilated or incised, if the patient's condition permits, or treatment can be postponed till a later date.

#### SUMMARY AND CONCLUSIONS

The literature on perineal phlegmon is reviewed, and an analysis of 36 cases is presented. Three cases are described in detail.

Perineal phlegmon is an infectious process and is not due to "extravasation of urine" into the tissues confined by Colles's fascia. The anatomic attachments of this fascia do not prevent the spread of the infection.

Stricture of the urethra and pyuria are often absent. A sloughing urethral mucous membrane, moreover, may mislead one into believing that stricture exists.

Smears and culture of the pus in the subcutaneous tissues, as well as blood cultures and renal-function studies, are necessary for successful chemotherapy and for a better understanding of the pathology of this disease.

Adequate surgical drainage, with decompression of the distended tissues, is imperative. Depending on the condition of the urethra, the retention of urine can be relieved by penile catheter, by perineal urethrotomy or by cystotomy.

## CLINICAL NOTE

SHAKING CHILLS IN  
TYPHOID FEVER\*

MARK AISNER, MD † AND LEO WAITZKIN, MD ‡

BOSTON

THE purpose of this report is to emphasize and to bring to the attention of clinicians the not uncommon presence of shaking chills in typhoid fever, either at the onset or during the course of the illness. The impression seems fairly well established in the minds of many physicians not only that chills are extremely rare but also that their presence in a given case militates against the diagnosis of typhoid fever. This concept is also found in many of the textbooks of medicine, whereas in others a very casual attitude is assumed concerning either the presence or absence of chills. The earlier writers on typhoid fever were well aware of the occurrence of chills, and one could not improve on a few excerpts taken from their writings. In an analysis of 303 cases of typhoid fever at the Massachusetts General Hospital from 1921 to 1835 Jackson<sup>1</sup> commented as follows:

In a very large proportion of cases chills occurred either at the commencement or late in the disease or both. It may not be useless, however to say that I do not find chills at an advanced or late period of the disease, to have been usually followed by very grave consequences though I had previously had a

of the onset of the disease. Now and again in the journals a case is reported in which chills have been a special feature, and the complication is spoken of as a manifestation of ague. He [Peabody] had also seen severe chills followed by elevation of temperature as a symptom of typhoid fever, which did not affect the subsequent course of the disease.

In the same report Osler classified chills in typhoid fever, and his classification and comments are worth repeating. Six categories were listed:

*Chills at the onset of the disease.* Seventy-nine cases were studied, 13 of which began with shaking chills. In 2 there were several severe rigors. Three patients had no chills, whereas the remaining 8 had single rigors.

*Chills at the onset of the relapse.* Two cases were described: the relapse in one having occurred on the sixty-fourth day of the illness and having been marked by several severe chills. In the other the relapse was ushered in by a severe single chill.

*Chills as a result of treatment.* Osler considered therapy to be the commonest cause of chills in typhoid fever, especially that following the use of antipyretics. A dose of 5 or 10 gr of antipyrine was sufficient to induce a chill in many patients. This observation was also noted by Janeway, whom Osler<sup>2</sup> quoted as follows:

If we give the modern antipyretics in large doses chills will occur, which are due simply to the fact that the temperature has been depressed and then it rises and this rise is accompanied by mild and sometimes by severe chills. Drop your antipyretics, and the chills disappear.

*Chills with the onset of complications.* A rigor may precede the development of any of the complications of typhoid fever. Among these, Osler listed pneumonia, pleurisy, acute otitis media, suppuration in the mesenteric

TABLE I Onset and Frequency of Chills in Patients with Typhoid Fever

CASE NO.	AGE	SEX	OCCURRENCE OF CHILLS	NO. OF CHILLS	COMMENT
1	21	F	First week	Single	
2	36	M	First week	Single	
3	22	F	First week	Two	Each chill followed by administration of 10 gr of acetylsalicylic acid
4	31	F	First and second weeks	Repeated	
5	35	M	First and second weeks	Repeated	
6	72	F	First, second and third weeks	Repeated	During third week the patient complained of pain in the right flank; there was dullness at the right base and basal rales were heard bilaterally
7	17	F	First and third weeks	Repeated	
8	39	F	Fourth week	Repeated	

different impression on this point. They are noted in 29 cases and only two of these were fatal in their termination.

Osler,<sup>2</sup> in his *Studies in Typhoid Fever* prepared at the Johns Hopkins Hospital and published in 1895, also recognized chills as part of the symptomatology of the disease.

In the systematic writers on typhoid fever scarcely a reference is found to chills, except as a symptom

of pyemic abscesses of the kidneys, perforation of the ileum or appendix and acute peritonitis. Chills were also noted in some cases of thrombosis of the femoral or saphenous veins. In rare cases they preceded the development of acute and fatal hyperpyrexia. On the whole, however, rigors were rarely present in the complications of typhoid fever.

*Chills (? septic) during convalescence in severe and protracted cases.* In a few cases, rigors were noted throughout the course of the fever, without any localizing symptoms or signs to account for them. Two cases were described in which severe chills occurred in the absence of any recognized complication. Both patients recovered.

*Chills due to concurrent malaria.* Osler considered this a very rare cause of chills in typhoid fever.

\*From the First and Third (Tufts) Medical Services, Boston City Hospital, and the Department of Medicine, Tufts College Medical School.

†Instructor in Medicine, Tufts College Medical School; physician in outpatient clinic, Boston City Hospital.

‡Formerly house physician, Boston City Hospital.

The significance of chills in typhoid fever was recently illustrated by a private patient who had repeated shaking chills during the first two weeks of his illness. We then became interested in the incidence of this symptom among patients with typhoid fever at the Boston City Hospital. A review of the cases from 1937 to 1939 inclusive showed that 7 of the 16 patients had had one or more frank chills, an incidence in this small series of 44 per cent. The time of onset and the frequency of the chills in these 7 cases, as well as in the 1 in private practice, are shown in Table 1.

It will be seen that 2 patients had a single chill at the onset of their illness. In 1 case, chills were directly attributable to medication. In 1 case, repeated rigors were experienced during the first two weeks, and these continued throughout the third week, during which, however, evidences of complications were present. In the remaining 4 cases, repeated chills were noted, extending from the first to the fourth week after the onset of the disease. It is interesting to note that in Case 5, in which the patient had repeated rigors during the first two weeks of his illness, signs of pneumonia at the left base, by both physical and x-ray examinations, developed in the third week, during which chills were entirely absent. It may be pointed out that the cases presented can readily be catalogued according to Osler's classification.

## CONCLUSIONS

In the study of any disease, it is essential to appreciate not only the common symptoms but also those that occur less frequently. This is particularly so in illnesses, like typhoid fever, which require isolation and special precautions. It is for this reason that we have considered it useful to discuss the occurrence in typhoid fever of shaking chills, as distinct from mere chilly sensations, either at the onset or during the course of the disease, and to correct an unjustified impression that seems prevalent among members of the medical profession.

In conclusion, one may quote from McCrae,<sup>3</sup> who, in his chapter on typhoid fever, stated:

... For the student it is most essential to realize that the classical description of the disease does not fit every patient and this makes it so important that the disease should be studied from the patient and not from text-books alone. No symptom or sign is necessarily present, a point never learned by some men who refuse to make the diagnosis of typhoid fever unless certain classical features are found.

## MEDICAL PROGRESS

### PSYCHIATRY: THE NEUROSES IN WAR

VERNON P. WILLIAMS, M.D.\*

BOSTON

IN considering the war neuroses, or what were labeled "shell shock" in the last war, the types and patterns of reaction do not differ from those encountered in peacetime, except in the precipitating factors. Of course, in war, more cases of such profound reactions as panic are seen. The experience of World War I gradually made it clear that emotional factors, fear of death, fear of and feelings of guilt about killing, conflict between duty and self-preservation, and so forth precipitated nervous disorders in soldiers, and that there was no tenable basis for considering physical injury to the nervous system, caused by shell explosions, responsible for the disorders.

Since, however, only certain men broke down nervously under the strain of war, there was a tendency in some quarters to regard the neurotic reactions as deriving essentially from cowardice, and consequently such reactions were sometimes treated summarily as weaknesses, requiring disciplinary action or at least disapproval. Considering the contagiousness of anxiety and hysteric reactions, when the general morale in a group is low, or when suggestibility runs high, there may well have been some justification and necessity for attempting to counteract them by disciplinary measures, particularly in acute situations that affected a group of men. There would be no more reason to treat the individual soldier by scolding and punishment than so to treat a civilian suffering with a neurotic disturbance.

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

\*Assistant in psychiatry, Massachusetts General Hospital

Yet, even in the present war, the psychiatric point of view is not always the guiding principle. Bowlby and Soddy,<sup>1</sup> in a letter written to the *Lancet*, relate their experiences as psychiatrists in a war neurosis center, where they were supposed to treat the victims of the Dunkirk evacuation. They complain that they were not free to practice psychotherapy because the director of the center held that the men were not mentally ill but needed discipline and "somewhat forceful encouragement." This attitude is not the prevailing one however, in the English hospitals, as attested by the numerous papers on psychiatric treatment. The matter is mentioned simply because in time of war, more than ever, efficiency, stamina, reliability, hardness and perseverance are essential, and it is quite understandable that some of those who themselves may have these qualities and who see the imperative need of them may get "fed up" with being tolerant of or sympathetic with reactions that certainly spell weakness in relation to the job that must be done.

#### ETIOLOGY AND PROPHYLAXIS

The etiology of the neuroses in war is important, for it is related to the question of prophylaxis, especially as applied to the establishment of an armed force of emotionally or nervously stable men. Statistical data on neuropsychiatric disorders that developed in the United States Army during World War I show that in a large percentage of such disorders there had been a history of nervous or mental instability or neurologic defect long before the men affected entered military service.<sup>2</sup>

Much has been written to support the theory that evidence of personal predisposition and a family history of nervous instability are predominantly found in men who become the nervous invalids in military life. On the other hand, it is claimed that the heredity factor in the mass of neuroses and psychoses is but slightly more than that for healthy individuals.<sup>3</sup> Concerning predisposition, Wittkower and Spillane<sup>4</sup> write, "A majority of psychiatric authors believe that, given sufficient emotional stress, neurotic symptoms may appear in anyone, and that the existence of neurotic symptoms in civil life predisposes to their re appearance in an increased and altered form in war . . ."

Kardiner<sup>5</sup> boldly states that psychoneurosis of the usual type, hysteria or compulsion neurosis is decidedly not a contraindication to military service. He rules out "positively only men with a history of convulsions, tiqueurs, stammerers and men who have shown persistent disturbances of the autonomic nervous system over a long period,"

and adds that "these, however, can be inducted and assigned to noncombatant duties." He makes the well known observation that many persons who were severely neurotic and maladjusted in pre-military life adjusted themselves well to the military routine and lost their neurotic symptoms—"for the time being, at any rate." But it is also known that many men with histories of neurotic tendencies did not make good soldiers, and thousands of them, together with the men who temporarily lost their symptoms and who regained them later, have been supported by the Government ever since.

Thus, it is very much of a problem, and one that has no satisfactory solution, to decide who should be excluded from military service on neuropsychiatric grounds. However, there is fairly general agreement that a history of psychotic episodes, long standing and disabling neurotic reactions, drug addiction, chronic alcoholism and severe mental defect should debar a man from induction. Just what degree of mental defect will be the line between induction and rejection is not clearly defined, and seems to depend on the judgment of the particular induction board.

Since it is impossible to predict accurately what man with a neurotic background will break down under the stress and strain of service, it is often said that the neurotic person should not be rejected from service but should be placed in the proper type of service for his particular qualifications and limitations. How such an equitable and ideal distribution could be worked out has not yet been settled. However, Sutherland,<sup>6</sup> in England, writes: "A new scheme has been developed whereby it will be possible to have psychoneurotic soldiers placed in work suited to them and, if necessary, near their homes. This highly commendable innovation will be followed with much interest." So far, the United States Army has made no provision for using the man who is rejected for neuropsychiatric disability.

Numerous psychiatrists are skeptical of the wisdom of returning a man who has broken down to active service when he becomes symptom free. Too often, these men have broken down again.<sup>7, 8</sup>

#### TYPES OF REACTION

The reaction patterns seen more frequently in the present war, as in the last, are anxiety, depression and hysteria. Following the evacuation of Dunkirk, many acute neuroses, typified by marked exhaustion, extreme anxiety or panic, developed. Many of the men affected had definite previous histories of nervous stability. This suggests that men of fairly sound personality may suffer neurotic breaks if the strain is severe enough.

A description of the acute war neurosis is given by Sargant and Slater<sup>9</sup>:

The clinical picture was surprisingly uniform. There were first the signs of physical exhaustion — thin, fallen-in faces, pallid or sallow complexions. The expression and the whole attitude of the body was one either of tension and anxiety, or of a listless apathy. Neurological signs of a functional nature were usually present. A coarse irregular tremor of the hands was exceedingly common; in some cases it resembled the tremor of extrapyramidal lesions, and in one it presented the typical pill-rolling form seen in chronic encephalitis. . . . The resemblance to a parkinsonian picture was often increased by an immobile facies, and the superficial resemblance was so great that a number of cases had been sent here under a diagnosis of parkinsonism — i.e., they had been thought to be organic. . . . Reflexes were usually exaggerated, occasionally sluggish.

The mental symptoms were those associated with acute anxiety, including sleeplessness, terrifying dreams, a feeling of inner unrest and a tendency to be startled by the slightest noise. Amnesia, especially for the worst part of the past experiences, occurred in some cases, and additional hysterical symptoms in others.

In the present war, as in 1914-18, the incidence of psychotic developments is much smaller than that of the neurotic reactions.

#### PSYCHOPATHOLOGY

Although the literature on psychiatric subjects published to date relating to the present war is not extensive, some of the papers have included interpretations of the psychopathology of the war neuroses. It seems unnecessary to look very deeply into mental mechanisms to find a satisfactory explanation of the breakdowns that occur, since it is only reasonable that a certain number of soldiers will collapse nervously under the strain and terrors of war. Why one man, and not another, goes to pieces brings up the whole question of what constitutes nervous, emotional or psychobiologic stability. In war situations, the fundamental conflict is surely between the drive for preservation of self and the impossibility of honorable escape, or of escape at all. Of course, many other factors operate psychologically for the individual person.

Sutherland<sup>6</sup> notes "fear of death and an impotent rage against what were felt to be overwhelming odds," and adds, "This rage was often excited to a paralyzing degree by the slaughter of women and children or by the loss of friends."

The same writer, who considers a principal feature of the deeper psychology to be a basically insecure attitude toward the outside world, observes: "This attitude was manifested in many ways, particularly in the excessive dependence

upon those figures with whom security was felt — namely, their families. It was as though these men had always unconsciously dreaded the assertion of their independence as a dangerous aggressive process." Sutherland believes that the significance of the so-called "separation anxiety" — from home and family — cannot be minimized.

Slater et al.<sup>7</sup> write, "The experiences of war provide a stimulus to aggressive and sadistic impulses, with the consequence that guilt and its associated depressive affect are very common; or projection mechanisms may come into play, the man believing that every 'plane is coming specially to punish him.'"

The relation between aggressiveness and anxiety is also commented on by Wittkower and Spillane<sup>10</sup>:

During war . . . not only was the general taboo on aggressiveness and violence diminished but they were forced by military service into situations which inevitably stimulated their aggressiveness and hence provoked anxiety. This anxiety is a signal of a threatened breakdown of defences against aggressive impulses. If further stimulation of aggressive impulses took place, a complete breakdown ensued.

The same authors describe a psychoanalytic portrayal of the type of personality subject to developing neurosis in war, as follows:

. . . a basic personality structure characterized by self-centredness, over-conscientiousness, lack of sociability and lack of affection for relatives and friends. Such individuals suffer from the feeling that their personality has been neglected and that their importance is not sufficiently recognised. Many of these men were unable to carry out their tasks in practical life; others, capable of doing this, showed little initiative, however, or energy. . . . This group often showed an effeminate disposition, were dependent on their wives and frequently weakly potent. Life in the trenches exposed them to a danger of death which constituted a threat to their excessive self-love. Community life ran counter to their asocial tendencies, and the unconditional demand for self-sacrifice in war called for a renunciation of narcissistic privileges. More so than others, individuals of this type were prone to conflicts about aggressiveness, and, through their latent homosexual tendencies, the exclusive association with men constituted a special stress. Under such stresses these individuals increasingly regressed to a narcissistic level of development, leading to a state of infantile helplessness, with a complete surrender to their suffering, and a need to be pampered, cared-for and petted like children. The withdrawal of object libido (diminished capacity for external interests and emotional ties) results in an inflation of ego libido (self-centredness), which is expressed in abnormal hypochondriacal sensations and a further diminution of genital potency.

Miller<sup>11</sup> says that a person of the narcissistic type is terrified at the prospect of a wound, that he is likely to develop hysteric manifestations, fugues

and, sometimes, major mental disorders: "They cannot face the horrors of war, not because their bowels yearn for the slain, but because they identify themselves with every mutilation and death which the soldier has to witness"

The drastic changes effected in a man's life by being taken away from the accustomed routine of home and civic life, the necessity for adjusting to discipline and comradeship not of his own choosing, and inadequacies of personality in successfully meeting the required adjustments constitute enough strain in themselves to induce neurotic reactions in some men. Add to these or, if these difficulties are not present in a very plastic person, introduce an intermittent and recurring threat of death or injury, and it will require hardness of personality structure, an idealism or philosophy that makes one's own life unimportant or a strong masochistic or sadistic tendency to bring the soldier through without the development of neurotic symptoms.

The appearance of anxiety symptoms in the presence of such a situation as the Dunkirk evacuation does not, of course, necessarily presage the beginning of a neurotic break. Many men recovered completely from such symptoms after a few days of rest, quiet and adequate food.

#### TREATMENT

Psychiatrists generally agree, from experience in both the last and the present war, that quick, immediate treatment is imperative. If treatment is delayed, the symptoms and neurotic patterns tend to become set. Slater et al.<sup>7</sup> state, "Treatment of an acute neurosis is almost as urgent as that of the acute abdomen." Writing of cases that had become chronic, they remark:

Conversion symptoms had been allowed to persist, and large periods of amnesia had been left untouched. By the time they arrived for treatment here the neurotic reaction had become fixed. . . It is of the utmost importance that the acute neurotic should receive effective first aid as soon as he is seen.

If the patient shows evidence of marked fatigue or exhaustion, physical care is the first requisite. Such care should include rest, complete rest in bed, if necessary; sleep, with the aid of sedatives, if necessary; narcosis for several days, if the degree of anxiety requires it; and a full diet and large quantities of fluids. As pointed out by Sargant and Slater,<sup>9</sup> the narcosis has to be arranged, of course, so that the patient can receive adequate diet and fluids.

If hysterical symptoms or amnesia are present, they should receive consideration. In some cases, a thorough history taking, accompanied by per-

suation or suggestion, is enough to effect relief. Abreaction is recommended if any areas of amnesia remain. Hypnosis may be used. In some cases, the use of a narcotic intravenously has been substituted, and successfully, for hypnosis. Stungo<sup>12</sup> uses a 10 per cent solution of Evipan Sodium, and Slater et al.<sup>7</sup> have used sodium amytal.

Modified insulin therapy has been found to be of value in some cases of anxiety, hysteria and moderate depression, especially when there has been a loss of weight and physical depletion. In general Sargant and Craske<sup>13</sup> describe the technique, whose purpose is to induce light coma with insulin and to give heavy feedings with sugar and potatoes. The writers do not claim great success, but state:

Rapid gains in weight and improvement in appetite may often be obtained in neurotic subjects whose general physique has deteriorated under stress. Generalized neurotic anxiety, and hysterical and depressive symptoms in a reactive setting sometimes improve rapidly. The improvement is mainly in the associated symptoms of nervous exhaustion.

They point out, wisely, that a stable psychological recovery may well depend on restoration of normal physique.

In some of the war neuroses, there must be an inclination, whether or not entirely conscious, to cling to symptoms to prevent a return to duty. Slater et al.<sup>7</sup> suggest

the desire of the patient to evade further military service can be used to aid recovery rather than to perpetuate illness, he can be told, for instance, that he will be recommended for discharge, but only when he has recovered from his symptoms. A healthy civilian is of more value to the country than a sick soldier.

McLaughlin and Millar<sup>14</sup> describe the effective use of air-raid noises in psychotherapy. At first, rather crude apparatus was used to simulate the sounds of planes, dive bombing, machine-gun firing and so forth. Then with the help of the British Broadcasting Corporation, gramophone records of actual warfare were produced.

Though the procedure was intended to be a means of conditioning cases to noxious sounds, it soon became evident that it could be used as a speedy and practical method of abreacting patients. The process of letting a patient relive terrifying emotional experiences has a therapeutic effect. As a measure for producing abreaction the employment of war noises is much simpler than hypnosis or hypnarcosis. It is quick, effective, and does not demand too great technical skill. The patient is enabled to recall terrifying incidents which had determined his symptoms, and by expressing them in the secure atmosphere of the hospital his self control and confidence are helped.

McLaughlin and Millar report that a number of cases were helped by this method.

## CIVILIAN REACTIONS

Reports on civilian reactions to air raids and bombing in England indicate that genuine air-raid casualties have been much lower than might have been expected. The general opinion seems to be that bombing has precipitated breakdowns in persons who have been predisposed to nervous instability.

Atkin,<sup>15</sup> in writing of 300 consecutive admissions to a mental hospital, says that air raids were regarded as having a major influence in only 4 cases and were contributory in only 6. He contends that to assert a causal connection between an air raid and the development of symptoms is "as logical as to maintain that horses are a cause of phobia for these animals or that open spaces are the cause of agoraphobia. It is a common and well-known mechanism for anxiety or fear to be displaced from some repressed object or situation to any convenient symbol at hand."

Brown<sup>16</sup> writes:

The swarms of hysterics which were by some expected to follow bombing have not appeared, but nevertheless there are certain psychiatric disorders attributable to air raids. The symptoms in mild cases of shock are tremor, sometimes violent, dilated pupils, and tachycardia, with an emotional state of fear, perhaps mixed with anxiety about relatives and property. There is usually extreme sensitivity to noise and considerable restlessness. . . . Some cases . . . are in a limp semistuporous state, usually with a tremor. These patients are acutely scared and seem to be groping for hysterical symptoms to give them peace of mind and forgetfulness of the incident.

Brown has rarely found definite psychoneuroses in patients who previously had no neurotic traits, and in rare cases, the form has usually been some type of hysteric reaction.

Certain patients with long-established neuroses, such as obsessional states and complex-determined anxiety, have been little affected by bombing. Brown quotes one patient as saying, "Oh, I'm not worried about the bombs—it's this queer tickly feeling in the back of my head." A woman with obsessional fears of murder and suicide and knives said, "I'm afraid I can't get very concerned about

bombs; I wish I could—it would be more normal." Brown gives a reasonable interpretation of such reactions:

The extraordinary toughness of some well-established psychoneurotics to aerial bombardment may be due to the fact that they are to some extent reassured by seeing other people being as worried as they have felt for years. Another reason may be that the whole of their emotional tone and affect is concerned with their own problems, usually related to sexual difficulties, and there is no affect left for simple bodily fear. In some cases the urgency of the moment does serve to inhibit the patient's long-standing emotional conflicts, with resultant clinical improvement. In the Russian revolution it was said that the obsessional psychoneurosis became extinct. . . .

Psychoses may be precipitated by bombing, and air raids have apparently induced episodes of depression or mania in persons who were known to be subject to the manic-depressive psychosis.<sup>17</sup> Patients who have long been sick with psychoses, however, are not likely to be affected by air raids. Treatment of the civilian casualties is much the same as that for the men in service.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 28081

#### PRESENTATION OF CASE

A twenty-three-year-old post-office clerk was admitted to the hospital because of intermittent pallor and weakness.

About eighteen months before entry, the patient became aware of pallor and slight general weakness. A local physician found the hemoglobin to be 35 per cent, and prescribed iron and liver-extract proprietaries. The patient improved for three or four months, and then relapsed soon after the discontinuance of the medicine. Another iron preparation was given by mouth, accompanied by injections of liver. At this time, the patient experienced a small amount of pain in the right side of his abdomen, occurring two to three hours after meals and relieved somewhat by defecation. About a year before entry, he consulted another clinic. Physical examination then revealed only pallor. Examination of the blood showed a red-cell count of 4,460,000 with 61 per cent hemoglobin, and a white-cell count of 7300. The red cells were hypochromic. The stools gave a strongly positive guaiac reaction on several examinations. Sigmoidoscopy and gastric analysis were both negative. Routine roentgen-ray examination of the gastrointestinal tract was negative; however, serial films with use of the Miller-Abbott technic finally showed a questionable polyp-like lesion near the cecum. When treatment was again stopped, the patient's hemoglobin fell to 48 per cent, rising again to 85 per cent with a red-cell count of 4,800,000 when iron therapy was reinstituted. The patient entered this hospital for an exploratory laparotomy.

On admission, the patient appeared husky, suntanned and well. There was a faint, blowing pulmonary systolic murmur. The heart, lungs and abdomen were otherwise normal.

The temperature, pulse and respirations were normal. The blood pressure was 114 systolic, 72 diastolic.

Examination of the blood showed a red-cell count of 5,450,000 with 15.5 gm. hemoglobin, and a white-cell count of 11,200 with 94 per cent polymorphonuclears. The blood Hinton reaction was negative. The urine was normal.

On the fifth hospital day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. THOMAS V. URMY: It seems safe to assume that the symptoms of pallor and general weakness that originally took this patient to his physician were due to anemia, and that the anemia was in turn due to blood loss from some lesion of the gastrointestinal tract. However, there is very little additional positive evidence to assist us in determining the type and exact location of the disease. It is known only that he had for a time, midway in the course of his illness, mild right-sided abdominal pain coming on two or three hours after meals and somewhat relieved by defecation. To this is added the information that serial films with the use of the Miller-Abbott technic about a year before the operation showed a questionable polyp-like lesion near the cecum, that is, I presume, in the lower ileum. The patient apparently had no sudden episodes of weakness or faintness followed by the passage of tarry stools. There was evidently no real intestinal colic, no diarrhea or constipation, and no epigastric pain, nausea, vomiting, heartburn or gas. When the blood count and hemoglobin were restored, his general health was apparently excellent. Physical examination revealed no mass or enlarged spleen or other sign to clarify the diagnosis.

Many gastrointestinal lesions may give rise to hemorrhage of considerable magnitude. In the upper portion of the tract, it might be esophageal varices, hiatus hernia, gastric or duodenal ulcer, gastritis, cancer of the stomach, or gastric leiomyoma or leiomyosarcoma. In the small intestine, one might encounter a malignant tumor such as lymphoma or cancer or a benign tumor such as lipoma, hemangioma, adenomatous polyp or leiomyoma; or an ulcer in a Meckel's diverticulum or, rarely, a simple ulcer of the ileum or jejunum. Very rarely, regional enteritis may cause massive bleeding. In the colon, extensive hemorrhage may come from ulcerative colitis, ulcerated polyp or cancer, particularly cancer of the cecum.

Many of these possibilities can be eliminated fairly readily. Barium studies did not reveal esophageal varices; and this, with the absence of an enlarged spleen or evidence of liver disease, seems definitely to rule them out. Hiatus hernia also may safely be eliminated in view of the negative x-ray examinations. Bleeding from gastritis must remain a possibility, although the absence of gastric symptoms is against it. The negative x-ray studies, the age of the patient, and the absence of pain and other local and general symptoms seem

local, appears to be perforation of the bowel, through either extension of the disease or radiation necrosis. She apparently died a respiratory death, possibly from pneumonia secondary to intra-abdominal sepsis.

What evidence have we for radiation necrosis? Sixteen months before entry, the patient had an operation. A cystic right ovary and tube were removed, and at that time a biopsy of the cervix was done. It is unfortunate that the biopsy was not done first. The diagnosis was epidermoid carcinoma, Grade III, and two months went by before any treatment was instituted. I am concerned about just what type of treatment was given. According to the record, roentgen-ray therapy was instituted, but no mention is made whether it was supplemented by intrauterine radium, which would make quite a difference. Obviously, the disease could not have been particularly evident to the eye, because they did the biopsy and then went ahead with a laparotomy to remove the tube and ovary. I think that one is justified in assuming that the carcinoma arose in the endocervical canal, and one may guess that by the time the patient reached the second hospital there was extension of the disease into the broad ligament, because of the slight hydronephrosis. As one continues, one finds that under treatment the hydronephrosis cleared. It may have been that the hydronephrosis was on an inflammatory basis, with sepsis giving rise to inflammatory nodes causing obstruction of the ureter, or disease may have been present that responded to radiation, thereby relieving the obstruction.

DR. TRACY B. MALLORY: The only additional information I can give you is that the patient was treated at the Pondville Hospital.

DR. PARSONS: That is very unfortunate, since I might have been responsible. However, I can now assume that the patient also had radium implantation because we believe at Pondville that roentgen-ray therapy alone, although it causes marked regression of the tumor, does not result in cure. One can get a perfectly extraordinary amount of regression of the tumor, and yet there will always be disease in the uterus unless the external radiation is supplemented by intrauterine radiation. Moreover, one should note that an operation was performed two months before the x-ray therapy. In other words, it is possible, particularly after the removal of the right tube and ovary, that the bowel became adherent at the site of the previous operation, and that as they cross-fired the radiation from one portal after another they continually hit the mesentery of a

single loop of small bowel or perhaps the sigmoid, resulting in radiation reaction to the bowel. Such a result often appears six months to years later, and is consequently a definite possibility.

Another interesting feature is that the patient was running a low-grade temperature, 99.5°F., for some time. There is no history of any previous bouts suggesting small-bowel obstruction. The obstruction is obviously not complete because on x-ray study of the abdomen no dilated bowel was apparent. Then, as a further suggestion along the line of radiation necrosis in the terminal stage, she passed 250 cc. of bright blood by rectum. Against the diagnosis of radiation necrosis and perforation is the fact that the usual picture of radiation reaction in either the small or the large bowel is one of marked thickening of the bowel wall. Whether perforation occurs in such lesions, I am not entirely sure. I have had one case of reaction in the sigmoid from radium alone in which the small bowel became adherent, resulting in perforation of the small bowel and localized peritonitis, the small bowel being involved through contiguity.

The other suggestion—that this might conceivably be due to uncontrolled cancer—is discarded if we believe in the form of treatment given at Pondville, where I treat such patients, but it is still possible that we had not controlled the disease. This was a rapidly growing, Grade III lesion. The upper part of the vagina was obliterated, and it was therefore almost impossible to tell whether disease was still present. Rectal examination did not reveal a mass and no blood was noted, but the record does not say anything about the degree of the fixation of the pelvis.

In conclusion, I believe that this patient had radiation reaction of the bowel and general peritonitis; the physical signs of a dilated stomach, probably due to ileus were present. On the other hand, she did not have dilated loops of small bowel. Although she had distant peristalsis, there was no spasm and no tenderness of the abdomen, which worries me a little bit. It is possible that she had an embolus and that the radiation reaction that I believe was present still did not have anything to do with her death. She had moderately low-grade fever, 99.5°F., and general malaise. She had been hospitalized for a previous operation, and it is possible that at that time she had a deep phlebitis and that death may have occurred from pulmonary embolus, the radiation reaction being an entirely secondary and incidental finding. I am inclined to go out on a limb, however, and say that this patient died of peritonitis and pneumonia, and that the peritonitis was due

to perforation of the bowel secondary to perforated radiation necrosis of the bowel or possibly perforation secondary to uncontrolled disease.

DR ALLEN G BRAILEY: Were x-ray films taken of the lungs?

DR MALLORY: I do not believe so.

#### CLINICAL DIAGNOSIS

Pelvic peritonitis.

#### DR. PARSONS'S DIAGNOSES

Peritonitis, secondary to perforated bowel, from radiation necrosis

Pneumonia

#### ANATOMICAL DIAGNOSES

Metastatic carcinoma, from carcinoma of the cervix.

Thrombosis of mesenteric, splenic and portal veins

Infarction of the small intestine, acute

Peritonitis, hemorrhagic, early.

Occlusion of cervical canal of uterus.

Pyometrium.

Cholecystitis, with cholelithiasis.

Operative wound, healed, right salpingo-oophorectomy.

#### PATHOLOGICAL DISCUSSION

DR MALLORY: The surgeons who took care of this patient on the wards were no more anxious to commit themselves than Dr. Parsons. They

thought that she probably had a pelvic peritonitis, but they did not specify the cause thereof.

At post mortem examination, it was found that nine tenths of the small bowel was completely necrotic, swollen, thickened and dark red and contained blood in its lumen. There was also free blood in the peritoneal cavity. The mesenteric, portal and splenic veins were completely thrombosed. The arterial supply of the small bowel was still apparently functioning. It was also found that the radium treatment had dealt satisfactorily with the local tumor. The cervical canal was completely obliterated. There was a pyometrium, but we could find no carcinoma in the uterus or immediate adnexa. However, the retroperitoneal lymph nodes were filled with metastases, one node was large enough so that it seemed to press on the mesenteric vein, and we thought that that, perhaps, was the immediate reason for the mesenteric thrombosis. However, it was merely a guess. I have not seen generalized venous mesenteric thrombosis result from radiation therapy and do not remember to have heard of it. I therefore doubt if the radiation was responsible. Certainly, there was none of the marked fibrous thickening of the bowel usually seen in radiation necrosis.

The lungs showed chiefly atelectasis and edema, although there was very slight beginning bronchopneumonia. There were a few other incidentals of not very great importance, the most striking one being a gall bladder containing a score of gallstones.

## A CHALLENGE TO FEDERAL, STATE AND LOCAL HEALTH DEPARTMENTS

WAR activities have produced some new health problems, but what is more important, they have served to focus attention on some old problems and to render certain ones more acute. The health of the soldier is vital, but so is the health of civilians, both because of the chance that soldiers may become infected from them, and because the urgency of producing articles of war demands that all workers be able to continue their tasks without absence due to illness.

Most problems that are arising are due to a shifting of populations. Not only are military forces being concentrated at given places, but to

care for their needs, concentrations of civil populations are built up in the areas immediately surrounding such military establishments. War industries are also causing concentrations of civilian populations at points where the plants are located. Frequently, because of such concentrations, water supplies become inadequate and have to be supplemented from sources less reliable than the regular ones. Facilities for community sanitation become overtaxed and create situations that may allow the spread of communicable diseases. Conditions are most acute in the boom-town areas, where thousands of people flock into communities that formerly consisted of only a few hundreds of inhabitants.

These conditions are a challenge to federal, state and local health authorities. If the health of the nation is to be safeguarded in these strenuous times, efforts must be redoubled, and vigilance should be kept at a high level to guard against unsatisfactory conditions. Steps have already been taken to meet the challenge. The personnel of the United States Public Health Service has been considerably expanded; liaison officers have been assigned to all the military areas to aid in arranging for the co-operation of medical officers of the United States Army and Navy and the civilian health authorities. Federal funds have been made available to expand the staff of many state health departments, and other sums have been allocated to assist in providing water supplies, sewerage and housing developments in the areas most acutely affected. Local health authorities have accepted their responsibilities and have increased their activities to guard the health of the newcomers to their communities.

The Honorable Paul V. McNutt, administrator of the Federal Security Agency, in an address before the annual conference of state and territorial health officers in Washington, D. C., last spring, called attention to three of the most critical problems of the immediate future: industrial hygiene, medical and hospital care, and nutrition. These three problems have already received the serious consideration of health authorities, and definite plans are being formulated to find the best solutions for them.

New England is fortunate in that there are few areas in which the problems are so acute as they are in other parts of the country. Water-supply systems and facilities for community sanitation have usually been provided to care for considerable increases in population, so that, up to the present time, few have been overtaxed. This should not, however, result in a false attitude of security, and every available means to guarantee the continued health of military and civilian populations should be utilized by federal, state and local health departments.

---

### KAREL FREDERIK WENCKEBACH

In the thunder and rumble of war, few people abroad and on this side of the Atlantic took notice that a heart had stood still that had been beating a lifetime for the benefit of countless other hearts. It was that of a man without whose work cardiology would not be what it is today.

Karel Frederik Wenckebach was born in 1864 in The Hague. After his graduation and a short interlude in anatomic and embryologic research he was compelled, for financial reasons, to give up his theoretical dreams and to go into rural general practice. His keen interest in scientific problems was not stifled; however. With a primitive sphygmographic apparatus, he made a series of fundamental discoveries, giving the first description and analysis of extrasystoles in the human heart and of disturbances in auriculoventricular conduction (*periodically dropped beats*).

His reputation became so outstanding that he was invited in 1901 to accept the vacant chair of clinical medicine at the ancient University of Groningen, Holland, an unprecedented honor for a young country doctor. A call to the University of Strasbourg followed in 1911, and in 1914 Wenckebach was appointed chief of the First Medical Clinic of the University of Vienna, which at this time was still one of the leading medical schools of the world.

Like most pioneers, Wenckebach had to overcome the opposition of more conservative groups of teachers, but with the appearance of his standard work on the cardiac arrhythmias in 1903, his

position among the prominent scientists of his time became firmly established. In this classic book, he stressed the fact that arrhythmias do not always indicate an organic lesion of the myocardium but that, on the other hand, they are apt to lead to cardiac failure. In the second edition, published in 1914, quinine was recommended as a useful drug in cardiac disorders for the first time since 1749, when Senac, a physician to the Court of Paris, prescribed it for obstinate palpitation; the action of the drug was rediscovered by a patient of Wenckebach, and its value in cardiac arrhythmias was proved by him. Although in this edition only one single electrocardiographic curve was reproduced, the epoch of both sphygmographic and electrocardiographic arrhythmia research was brought to a successful conclusion in Wenckebach and Winterberg's monumental monograph, which appeared in 1927 and is still unsurpassed.

Wenckebach's work on the beriberi heart, carried out in the Dutch East Indies in 1929-1930, was the forerunner of the present conceptions regarding vitamin deficiencies in the circulatory system. His widely appreciated book on cardiac failure gave further proof of his keen clinical observation.

All in all, Wenckebach was one of the founders of modern cardiology. Many of his basic discoveries became so soon accepted as commonplace facts that their origin fell into undeserved oblivion. However, some of these are even today connected with the name of their discoverer: the "Wenckebach periods," the "Wenckebach bundle" and the "Wenckebach sign" of adhesive pericarditis.

The First Medical Clinic of Vienna was for years the goal of numerous European and American graduate students, in the fields of both cardiology and general internal medicine. Important diagnostic and therapeutic achievements originated under Wenckebach's guidance, such as the discovery by Saxl of the powerful diuretic effect of certain soluble mercury compounds, which greatly facilitates the treatment of congestive heart failure.

Wenckebach was by no means a dull, dry professional man, absorbed in scientific problems. His active interests roamed far and wide in the realm of the arts and literature, and his beautiful home,

with its choice paintings, sculptures and pottery, was an international center of intellectual and artistic life. His unusually charming and lovable personality, as well as the enormous dimensions of his private practice, brought him into close contact with a large number of Europe's most interesting people. A perfect gentleman, with a liberal, open mind, he knew how to enjoy life in a noble, refined way and also how to make it enjoyable for others.

Wenckebach's intimate friendship with outstanding British investigators, such as Mackenzie and Keith, enabled him to visit London after World War I, while the blockade was still in effect, to secure food transports for the starving Austrians and to save the famous Gobelin tapestries in Vienna from being sold for bread. After having completed a lecture tour through the United States in 1923, he often referred enthusiastically to the idealism and unbiased critical spirit of American scientific workers, which impressed him even more than the amazing technical facilities available in this country, and in his last letters to former pupils he expressed a hopeful belief in the present and future leadership of American medical research.

MEDICAL EPONYM

MORTON'S TOE

Thomas G. Morton (1835-1907), surgeon to the Philadelphia Orthopedic Hospital, described this condition in a paper, entitled "A Peculiar and Painful Affection of the Fourth Metatarso-Phalangeal Articulation," published in the *American Journal of the Medical Sciences* (71: N. S.: 37-45, 1876). He reported 15 cases, 13 of which were in women. All the patients complained of severe pain localized in the fourth metatarsophalangeal articulation. It was generally relieved by removal of the shoe. Some patients told of having to stop in the street for this purpose. Morton advised operation for the relief of chronic cases. The origin of the condition is described as follows:

To the peculiar position which the fourth metatarso-phalangeal articulation bears to that of the fifth, the great mobility of the fifth metatarsal, which by lateral pressure is brought into contact with the fourth, and lastly, the proximity of the digital branches of the external plantar nerve, which are under certain circum-

stances liable to be bruised by or pinched between the fourth and fifth metatarsals, may be ascribed the neuralgia in this region.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MATERNAL WELFARE

CAUSES OF MATERNAL DEATH IN  
MASSACHUSETTS DURING 1940 (concluded)

Table 1 gives the final and correct classification for maternal deaths occurring in Massachusetts during 1940. Since the publication of the original table in the January 8 issue of the *Journal*, 2 cases have been added; but because the 2 deaths in women who were not pregnant have been dropped, the total (219 deaths) is the same. The most striking conclusions to be drawn from this study are covered by the following paragraphs.

There were 58 autopsies. This number is somewhat less than that for the cases in 1939. The value of autopsy cannot be emphasized too strongly. In certain cases, in no other way may an exact diagnosis be arrived at. It would be very

TABLE 1. Causes of Maternal Death.

CAUSE	NO. OF DEATHS
Sepsis	50
Medical diseases	42
Embolism	29
Hemorrhage	27
Eclampsia	24
Surgical conditions, including shock	15
Transfusion reaction	8
Rupture of uterus	8
Anesthesia	8
Ectopic pregnancy	6
Pernicious vomiting	2
Total	219

helpful, as well as informative, if the medical examiners used their authority in demanding autopsies on cases of maternal death that came under their jurisdiction. Red tape and sentiment are the reasons why more permissions for autopsies in this group are not obtained. Several of these cases had only a clinical diagnosis, which would undoubtedly have been proved false could an anatomical diagnosis have been made.

Reference has previously been made to the diminution in the number of deaths due to sepsis, and to the large percentage of deaths due to criminal abortion. Chemotherapy undoubtedly has played a large part in this fortunate decline. Undoubtedly, also, improved obstetric operating and an absence of bungling operating have been contributory.

Among the medical deaths, those definitely attributed to pneumonia emphasize the value of the

treatment of the common cold and the necessity for early diagnosis of pneumonia if chemotherapy is to be of any value. Heart disease has been proved to be a serious complication of pregnancy, as the number of patients who died undelivered bears evidence.

Several of the cases allocated to embolism may have been preventable. Undoubtedly, some of these cases had a low-grade phlebitis that was not recognized, and might have been treated successfully by surgery. Such methods of treatment, however, are new, and the patient must be treated only by surgeons particularly trained in this field.

The deaths attributed to hemorrhage are so closely allied with transfusion, or the lack of transfusion, that the two may be discussed together. It was surprising how many of the patients who died of frank blood loss were not given the benefit of the injection of whole blood. Blood banks are not yet established in some of the large municipal hospitals, so that one cannot criticize the lack of them in small, local institutions. But whole plasma is on the market, and although it does not always take the place of whole blood, it certainly tides the patient over in many cases that would otherwise result fatally. The 8 patients who died of transfusion reaction, of course, represent a very small percentage of the cases in which transfusion was used. And yet one cannot help believing that in some institutions the technic of matching and cross-matching has not been properly developed.

Under the cases allocated to eclampsia, some bring out the fact that many women in Massachusetts still have no prenatal care. Practically none of these women should have died. In only 1 case did poor obstetric operating play a major part in the fatality, but in many, unintelligent procrastination on the part of the medical attendant was the real reason for the death.

There is little to be said of the cases allocated to surgical conditions, which include mesenteric thrombosis, appendicitis, intestinal obstruction and surgical shock. Once more, it should be emphasized that intestinal obstruction does not lend itself to delay.

Several of the patients with rupture of the uterus died because of poor obstetrics, particularly those who died undelivered. Such fatalities can in no way be condoned. And those patients with rupture of the uterus, at the beginning of labor, on whom cesarean sections had previously been done, emphasize that such ruptures do occur, and that if one chooses to allow these patients to go through labor, they should be hospitalized at the very first sign of labor and watched very carefully, with the understanding that a laparotomy may be necessary.

The 8 deaths due to anesthesia are far too many; of course, all were preventable.

Under ectopic pregnancy, the unusual case of abdominal pregnancy has previously been mentioned. Any abdominal pregnancy is a serious condition. In this case, the diagnosis was entirely missed. The 5 patients with tubal pregnancies who died of massive hemorrhage, without operation, show how serious the condition may be; there must have been previous bleeding that went unrecognized, either because of the patient's ignorance or because of the ultraconservatism of the physician.

That pernicious vomiting may still cause death means only that patients are ignorant or negligent in reporting to their physician, or that the physician is ignorant or unintelligent in his treatment of this complication.

The committee once again expresses appreciation for the time and energy spent by the physicians who investigated these deaths in different parts of the State. It also thanks the physicians interviewed for their willingness, almost without exception, to co-operate with the investigators. The deaths for one more year, 1941, remain to be classified, and the investigation is now under way. The national emergency will make this study more complicated, because some of the physicians whose cases resulted fatally will have been called to war. This is appreciated, but under these circumstances, hospital authorities are requested to instruct their record departments to be most lenient in allowing investigators, who sometimes have come many miles, to look up facts about these cases. Unfortunately, there has been hesitancy to grant this privilege in the past.

#### "TUBERCULOSIS IN CHILDREN"\*

It might be interesting to those who are listening if I simply stated a few of the questions most frequently asked by the parents and other relatives of patients at the Children's Hospital when the question of tuberculosis is raised. Some points recur so commonly under those circumstances, and we have had to explain some things so often, that I am sure many people lack information about them.

The first question asked is, Do children or babies really have tuberculosis? The answer is obviously that they do, and also that they have it oftener than the public realizes. The way tuberculosis shows itself (or fails to show itself) differs in child patients from the way it acts in adults, but children and even babies as young as a few weeks of age may and indeed do have the disease.

Another question often asked is, Do they inherit it? The question may be asked in another way, when the

\*A "Green Lights to Health" broadcast given through Station WAAB by Dr. Clement Smith on November 29, 1941, and sponsored by the Public Education Committee of the Massachusetts Medical Society and the Massachusetts Department of Public Health.

parents of a tuberculous child say: "None of my relatives have tuberculosis; I don't see how my child could have gotten it." To answer the last statement first, it may be pointed out that one of the very important things about this disease in general is that many tuberculous people have so few symptoms or such indefinite symptoms that they do not suspect that they are ill. But beyond that point, it should be said that the disease is not inherited by children. Physicians often say, and probably with reason, that although tuberculosis itself is not passed on from generation to generation, some families seem to inherit a susceptibility to it, or seem by virtue of their inherited constitution to be likelier to develop it, but the actual condition of being born with the germ of tuberculosis in the body, although even that occurs very rarely, is, generally speaking, not the way babies get tuberculosis. Tuberculosis comes from tuberculosis, not by inheritance but by catching the germs of the disease just in the same way that whooping cough is caught from someone who has whooping cough. It may take a good deal of contact with a tuberculous person to infect a child with the disease, but not necessarily, since perfectly definite cases have been traced to only one meeting between an uninfected child and a diseased adult. Undoubtedly, numerous cases of infection occur quite by chance in crowded places, — when children are taken into streetcars or stores, or places of amusement, — since the more people a child is in contact with, the more probable it is that some of them may be harboring the germs that may infect the child. But by all odds, the commonest single place where children and babies acquire tuberculosis is in the very place where they ought to be safest, that is, in their own homes, and this is a strange thing when one thinks that traditionally the home constitutes the barrier that parents build as the one place of refuge for their children against the dangers of the world. Of course, the source of the infection at home is usually an older person, who either has the disease and refuses to do anything about it or, more commonly, has it and is not aware that he has it. One leading professor of children's diseases has made the very true statement, "There are two ways to find that a man has tuberculosis — one is to find the germ in his sputum, the other is to find the disease in his baby." This is equally true, of course, of a mother.

A fourth question is asked in this way: "I don't see how the child can have tuberculosis, Doctor, because he has never been sick. In fact, he is one of the healthiest-looking children in his school. He is not thin, he's full of energy, and he doesn't cough." That question brings up the whole peculiarity of tuberculosis in general, and particularly of the disease in children and babies. As you know, it may smolder in adults like a concealed fire somewhere under the surface and without any signs of itself until gradually it progresses to a stage where symptoms occur. At first, these are very indefinite ones of tiredness, loss of weight and so forth. In babies and children, this peculiar lurking quality of tuberculosis is even more evident, so that we find it to be present, and quite often present to a rather widespread degree, in children who are fat and happy, and have no cough or other symptoms. Therefore, a very important thing about handling the tuberculosis problem in childhood and infancy is that we must look for the disease before it has gone far enough to show the signs that the public usually associates with it. One tragic thing is that often in young babies the first outward symptoms that a mother or father observes may be the indications that the disease has gone beyond the

point where there is any hope of bringing about a recovery.

A fifth question, which follows from this former one is, of course, How can the disease be found before any symptoms appear? Fortunately, there are several very good procedures for doing this, none of which take very much time or trouble. Of course, one thing of prime importance is to apply these procedures, if not to all children in the population, at least to children whose parents or relatives are known to have the disease and who might thus have been exposed to it.

The means of searching are first of all the simple and highly reliable tuberculin test, which as performed at present requires a nearly painless needle prick, although a method is now being developed that avoids even the needle prick by simply applying the testing substance against the skin under a strip of adhesive tape for a few days. No particular danger or discomfort is associated with either of these tests, even if a reaction develops. If properly performed and interpreted, the test should pick out practically all the children into whose bodies the germs of tuberculosis have entered. The ones who show that this has happened can be given an x-ray examination of the chest, to reveal whether the infection is in a severe state, or whether it is so mild as simply to need repeated examinations during the course of childhood.

And, since in considerable part the danger is determined by the x-ray findings, this naturally leads to the sixth and very crucial question on the part of the parents and relatives, "How dangerous is tuberculosis in a baby or child?" This question must be answered in a particular and not a general manner, because so much depends on the age of the child and on how far the disease has progressed before it has been discovered. In general, it may be said that all babies up to the age of two or three years do not do so well with the disease as older children do, so that there exists a high point of greatest danger during the second year of life. After this, the danger diminishes a good deal, so that between the ages of seven and twelve children seem to have a remarkable resistance, at least to tuberculosis of the lungs. After that, when children, particularly girls, get into the teens, the resistance is lessened and the outlook for a tuberculous child of fourteen or fifteen may become as serious as that for a tuberculous infant. But even in infants who have not much resistance if we can discover the infection early and get the child under care at that time, certainly at least 90 per cent of patients will do well. On the other hand, if the disease is not brought to attention until symptoms develop, the figure may be nearer 50 per cent, with a much greater number of children who do not survive — a striking example of the value of finding the infection early in those babies and children who acquire it.

How long does it take to get better? That is not an easy question to answer, but we have noticed at the hospital that, if a child is doing well twelve months after we first find the disease, we can expect him to do quite well thereafter; therefore, we can tell parents (even the parents of small infants in a dangerous age) that when we have known their child for a year we can give them a much brighter outlook. But we can never drop an infected child from some sort of care then or even thereafter. We do not need to keep the child an invalid, but we consider it proper for all these children to be examined once a year through childhood and adolescence, and preferably until they are at least twenty-five years old for the sort of insurance that an annual examination gives. At such annual examinations, during adolescence, it may

be wise to take an x ray film for checkup purposes. In the safer age period of midchildhood, repeated annual x ray studies are probably not required. Of course, these children do not need to be invalids all this time, and almost all, after the critical first year has passed (and some times before that), can be allowed to lead perfectly normal lives.

What is the best treatment for babies and children with the disease? Unfortunately, we have no medicine that kills the tuberculosis germs at present, although we live in hope. Some children, particularly those in whom the lungs are diseased in adolescence, may need special air injection treatment to rest the involved lung. In the large majority of patients, all we can do is to believe that bringing about the best possible state of general health for the child will offer him the greatest chance for complete permanent recovery. This may mean cure in a sanatorium; it may mean rest at home, it may mean special medicine and diet to build up the child or it may mean that the child is already in such good household surroundings that we need do little further except to supervise the parents' care. But that brings up another important thing—which is that the child should no longer remain in contact with diseased adults who may be passing on the infection to him, so that one very important thing that we can do just as soon as we find an infected child is to make sure that no one in the household is (either knowingly or unknowingly) diseased and thus acting as a source of germs that may be passed further to the patient. This requires co-operation on the part of the parents and a certain amount of work in arranging for examinations, but in the long run it is helpful not only to the child but to the parents, and of course to any other children in the family.

In conclusion, it is appropriate to bring up the question, How are these things done? In Massachusetts, they are done in part by an expert body of state and city workers, who, fortunately, have a very well staffed and well-equipped group of hospitals and sanatoriums to which patients may be sent. But by no means does all the budget for this kind of work come from the state and municipal funds, in fact, a large part of it comes from the Massachusetts Tuberculosis Association and is supported by the Christmas Seal sale. In the numerous jobs that have to be done to straighten out the family situation and to heal and to protect the child with tuberculous infection, we are constantly helped by things that the Christmas Seal sale has made possible. If it becomes necessary to send the child to a more healthful environment than he can have at home, we may find care for him in such a place as the Prendergast Preventorium, which is actually supported by the annual Seal sale. If it is necessary to help his convalescing father to find work, the Sheltered Workshop, which is also supported in this way, may be of assistance. There are many other important ways in which the money that you pay for Christmas seals reaches the situation in a way that makes you yourself an effective agent in meeting problems that are commoner than you may realize.

## DEATHS

**DALTON**—CHARLES H. DALTON, M.D., of Somerville, died February 12. He was in his sixty-sixth year. Born in Charlottetown, Prince Edward Island, Dr. Dalton received his degree from McGill University Faculty of Medicine in 1901. He was on the staff of the Somerville Hospital, and was a fellow of the Massachusetts Medical Society and the American Medical Association. He is survived by his widow and five sisters.

**WAKEFIELD**—ARTHUR PAUL WAKEFIELD, M.D. of Belmont, died February 6, in his sixty-fourth year. Born in North Bloomfield, Ohio, he graduated from Hiram College in 1900 and received his M.D. degree from Rush Medical College in 1904. After a brief period of private practice, he went to China as a medical missionary and remained there for twenty-two years. He was in charge of a hospital in Luchowfu from 1912 to 1916 and then became director of student health at Boone University at Wuchang. This position he held until the Chinese revolution of 1927 made it necessary for him to leave the country. The Chinese National Red Cross decorated him for flood relief on the Yangtze and reconstruction work at Wuhu. On his return to America, he supervised the school clinics conducted by the Massachusetts Department of Public Health for five years, and then became superintendent of the Central Maine Sanatorium at Fairfield. He returned to the Massachusetts Department of Public Health in 1937 and was given the task of organizing and directing the Clinics for Crippled Children. Under his guidance, these clinics have been very successful in bringing aid to hundreds of handicapped children. His crusading spirit, kindness and persistency in the face of obstacles made him exceptionally well qualified for this type of work.

His widow, a son and two daughters survive him.

## WAR ACTIVITIES

### CIVILIAN DEFENSE

#### RELATION OF RED CROSS CHAPTERS TO DEFENSE COUNCILS

A joint statement of policy governing the relation of Red Cross chapters to state and local defense councils, as developed by the Office of Civilian Defense, Office of Defense Health and Welfare Services, and the American Red Cross, was issued December 28 and published in *Victory*, the official weekly bulletin of the agencies in the Office for Emergency Management, as follows:

I. The Red Cross through its chairman is a member of the Civilian Protection Board has made available all of its services as needed by the United States Office of Civilian Defense and state and local defense councils. As illustrative of its national services, attention is called to the programs involving blood plasma, medical technologists and nursing enrollment. The Office of Civilian Defense and the American Red Cross are agreed that defense councils and Red Cross chapters should develop local plans of co-operation in their civilian-defense activities.

II. Recognizing the basic responsibility of government, it is the duty of every Red Cross chapter and branch to aid in the most efficient marshalling of the community's resources. It is agreed that duplication should be avoided in these services and training courses required in civilian defense activities and that the long-established nationwide program of the Red Cross should be utilized to the fullest extent.

III. Services required in civilian-defense activities will be made available by chapters to defense councils in accordance with the policies herein stated. Chapters will co-operate to the fullest extent and, during the period of emergency, will operate subject to the authority of the defense councils or appropriate governmental officials. The Red Cross at all times will maintain administrative and financial control of its immediate operations.

IV. Chapters should expand Red Cross services and training courses within the scope of their responsibility.

so that they may be prepared to give such services as are needed in the local programs of defense councils.

V. In the specific application of the above general policies, it is agreed that the areas of Red Cross responsibility shall be:

1. Red Cross chapters will be prepared to function, in the following fields of activity in full co-operation with all public and private agencies:

*a.* Disaster relief—training and service—food, shelter, clothing and other necessities of life in the event of disaster, whether occasioned by belligerent action or other cause.

*b.* First aid—training.

*c.* Nurse's aides—training and service.

*d.* Red Cross home nursing—training.

2. Red Cross chapters will assist defense councils in the following fields on the basis of mutual specific agreements as to lines of responsibility:

*a.* Disaster relief—service—will assist local defense councils in rescue work and emergency medical care.

*b.* Nutrition aides—training and service.

3. Red Cross chapters will make available to defense councils as needed the services of the following volunteer special service units, which shall at all times maintain the Red Cross unit organization (see III above):

*a.* Motor corps—service.

*b.* Production corps—service.

*c.* Staff assistance corps.

*d.* Canteen corps and canteen aides—service.

*e.* Hospital and recreation corps—civilian hospitals—service.

4. Red Cross chapters in their services to the armed forces are fully responsible for the following activities:

*a.* Information and claims—service.

*b.* Communications and reports.

*c.* Consultation on personal and family problems.

5. The functions of Red Cross chapters adjacent to Army posts and Naval stations include the following:

*a.* Hospital recreation corps—training and service—in military hospitals.

*b.* Motor corps—training and service—service originating on military reservations.

*c.* Production corps and staff assistance corps—activities on military reservations.

*d.* Participation in Red Cross camp and hospital-service councils.

6. Junior Red Cross:

*a.* The participation of boys and girls in elementary and secondary schools in Red Cross services through Junior Red Cross programs should be maintained in the same relation to local defense councils and to the armed forces as is established in this statement with respect to its parent organization. Junior Red Cross activities will be channeled through the local Red Cross chapter.

*b.* Red Cross chapters will make available to defense councils as needed those activities of the Junior Red Cross which contribute to the health, welfare and unity of schools and communities.

## NEW HAMPSHIRE MEDICAL SOCIETY

### DEATHS

DAUDELIN—ALFRED DAUDELIN, M.D., of Nashua, died September 21. He was in his sixty-fourth year.

Born in Nashua on June 6, 1878, Dr. Daudelin received his degree from Baltimore Medical College in 1908. After practicing in Somersworth, he returned to Nashua, where he held memberships in the county medical association, the New Hampshire Medical Society and the American Medical Association. He served on the Nashua Board of Health for several years, and was a former city and county physician.

His widow, Mrs. Eugenie Daudelin, and a sister, Miss Phoebe Daudelin, survive him.

DEMING—ROBERT M. DEMING, M.D., of Glenduff, died January 28. He was in his forty-ninth year.

Born in Elizabethtown, New York, Dr. Deming attended Colgate University and received his M.D. degree from University of Vermont College of Medicine in 1916. He served for two years with the British Medical Corps in World War I. He was superintendent and medical director of the New Hampshire Tuberculosis Sanitarium, and was a member of the National Tuberculosis Association and a fellow of the New Hampshire Medical Society and the American Medical Association.

He is survived by his widow, Mrs. Lolita Smith Deming, and his mother, Mrs. Mabel S. Deming, of Ballston Spa, New York.

SANBORN—BENJAMIN E. SANBORN, M.D., of Manchester, died October 3. He was in his fifty-seventh year.

Born in Deerfield, Massachusetts, in 1885, the son of Benjamin E. and Alice (Johnson) Sanborn, Dr. Sanborn received his degree from Dartmouth Medical School in 1911. He spent the next three years as an intern at the Massachusetts State Hospital and at the Rhode Island Hospital, and established his medical practice in 1914. He was a member of the New Hampshire Medical Society and the American Medical Association.

He is survived by his widow, Mrs. Shuah Hobbs Sanborn.

## MISCELLANY

### TEWKSBURY STATE HOSPITAL AND INFIRMARY

Dr. Lawrence K. Kelley has recently resigned as superintendent of the Tewksbury State Hospital and Infirmary; he plans to re-enter private practice. To date, the vacancy has not been filled by the trustees of the institution.

# RESUME OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR DECEMBER, 1941

DISEASES	DECEMBER 1941	DECEMBER 1940	FIVE YEAR AVERAGE*
Anterior poliomyelitis	7	0	1
Chicken pox	1603	1680	14 0
Diphtheria	19	9	18
Dog bite	577	591	559
Dysentery bacillary	16	3	13
German measles	68	48	53
Gonorrhea	273	294	423
Measles	678	1165	1101
Meningitis meningococcal	12	7	6
Meningitis other forms	6	—	—
Mumps	1460	597	475
Paratyphoid infections	4	1	3
Pneumonia lobar	708	407	437
Scarlet fever	1171	642	648
Syphilis	335	376	412
Tuberculosis pulmonary	228	314	264
Tuberculosis other forms	28	28	29
Typhoid fever	8	6	8
Undulant fever	3	5	5
Whooping cough	828	1161	983

\*Based on figures for preceding five years

## GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Easthampton, 4, Fort Devens, 1, Hardwick, 1, Somerville, 1, total, 7

Anthrax was reported from Lynn, 1, total, 1

Diphtheria was reported from Boston 2, Everett, 1, Fall River, 8, Lowell, 1, Norfolk, 1, Palmer, 1, Somerville, 1, Springfield, 1, Stoughton, 1, Taunton, 1, Webster, 1, total, 19

Dysentery, bacillary, was reported from Boston, 1, Brockton, 1, Easthampton, 3, Fall River, 2, Northampton, 1, Waltham, 8, total, 16

Encephalitis, infectious, was reported from Haverhill, 1, total, 1

Meningitis, meningococcal, was reported from Boston, 2, Brockton, 1, Fitchburg, 1, Framingham, 1, Gloucester, 1, Mendon, 1, Milton, 1, New Bedford, 1, Norwood, 1, Waltham, 1, Worcester, 1, total, 12

Meningitis, other forms, was reported from Gloucester, 2, Haverhill, 1, Norwell, 1, Salem, 1, Waltham, 1, total, 6

Paratyphoid infections were reported from Marblehead 1, Medford, 1, Salem, 1, Westwood, 1, total, 4

Pellagra was reported from Boston, 1, Quincy, 1, total, 2

Septic sore throat was reported from Boston, 6, Boxford, 1, Cambridge, 1, Everett, 1, Fall River, 3, Greenfield, 1, Malden, 1, Plymouth, 1, West Springfield, 1, total, 16

Tetanus was reported from Wakefield, 1, Woburn, 1, total, 2

Trachoma was reported from Worcester, 1, total, 1

Trichinosis was reported from Attleboro, 5, Camp Edwards, 3, Chelsea, 2, Everett, 1, Wakefield, 1, total, 12

Tularemia was reported from Lawrence, 1, total, 1

Typhoid fever was reported from Boston, 3, Chelsea, 1, Danvers, 1, Newton, 1, Stoughton, 1, Wellesley, 1, total, 8

Undulant fever was reported from Boston, 1, Northbridge, 1, Webster, 1, total, 3

Mumps continued to show record high incidence for the sixth consecutive month

Bacillary dysentery, chicken pox, diphtheria, dog bite, German measles, meningococcal meningitis, paratyphoid infections and scarlet fever were reported above the five year averages

Typhoid fever was reported at a figure equal to that for the five year average.

Measles, pulmonary tuberculosis, tuberculosis, other forms, undulant fever and whooping cough were reported below the five year averages

Lobar pneumonia showed record low incidence

The focus of animal rabies which has been noted in the northeastern section of the State is still active in Middlesex County, cases having been reported from Burlington, Wilmington and Woburn

## REPORTS OF MEETINGS

### SUFFOLK DISTRICT MEDICAL SOCIETY

At the regular fall meeting of the Suffolk District Medical Society, October 22, presided over by Dr Albert A. Hornor, Dr Harold C. Stuart discussed 'Experiences in Unoccupied France during 1940-1941'. The Rockefeller Foundation, which for sixteen years had been at tempting to develop an efficient public health service in France, withdrew at the beginning of World War II, only to return following the fall of France, it was to establish such a service that Dr Stuart, among others, was asked to go to France. He recounted the delays and in conveniences caused by the lack of co-operation by the civil authorities, although promises had been given and arrangements made many months before. But finally he and his associates were able to set up a sort of regional institute at Marseilles

Some idea of the state of affairs in Marseilles may be gleaned from a comparison with a city such as Boston, of approximately the same population. In the first place, 500,000 refugees entered the crowded city, then the confiscation of 140,000 freight cars from France (with as much cattle and produce as they held) markedly decreased the facilities for transportation of people and food, the lack of fuel further limited the amount of travel, even though some compensation resulted later from the conversion of larger trucks and buses into wood burners; even power plants were curtailed in fuel, thereby further limiting tramway travel. Two million five hundred thousand prisoners in Germany decreased the manpower to critical levels and made the task of those remaining more difficult. Recreation was so restricted that people went to drab cafes and dull theatres only to take advantage of the warmth afforded by the crowds. The existence for foreigners was particularly trying, since they could obtain no work without a citizen's certificate nor any relief from the community. The eventual result was their getting into trouble and being sent to concentration or work camps, in which the living conditions were inconceivably bad, no attempt to improve them being made.

In regard to the food situation in Marseilles, which was the particular problem of Dr Stuart, the most notable lacks were of animal proteins and fats. This was especially trying on infants and children, who were allotted one and a half pints of milk below eighteen months of age and one pint between eighteen months and five years. Nobody over five years was allowed milk at any time, and even the above schedule far from assured the children sufficient milk. Bread rations were decreased from 350 to 240 gm per day, 90 gm of almost inedible goat and horse meat was allowed about twelve times a month, 15 gm of vegetable fat a day, 1 pound of sugar a month, and 20 gm of cheese, which was considered a real delicacy, five times a month. Obtaining food was usually the most difficult task, often requiring a three hours' wait to obtain little or no food. Therefore, Dr

Stuart and his group stayed in hotels where the more placid and acclimated natives endured the delay.

For the scientific study that was carried on, the group attempted to obtain a crosssection of the population and to measure the intake of various foods. There were 100 families, in addition to 100 children (for age distribution), so studied, and appropriate blood studies were carried out. Incidentally, most of the equipment arrived from America either very late or not at all. The subjects were observed for intake in the home, and then underwent a physical examination at the clinic. Although citrus fruits were virtually unknown, and the blood ascorbic acid levels were invariably zero, no examples of true clinical scurvy were found. Vitamin A levels were also low. The protein values, on the other hand, were not appreciably lowered, and the erythrocyte and hemoglobin counts were satisfactory. The failure of iron-deficiency anemias to occur was attributable to the importation of boatloads of green vegetables from the African colonies during the winter and spring. The high phosphatase levels could be expected from the high incidence of rickets, which was not much different from that in prewar times. The results of these preliminary studies were about what might be expected in a country where a severe shortage has been felt for only a relatively short period. There were many early manifestations of deficiency syndromes, and more recent reports indicate that severer deficiencies are already appearing and promise to become commoner during the winter.

Dr. Stuart described the relief work being carried on by the Swiss and American organizations, which act in the role of medical advisers to the population. In this manner, the relief workers were able to obtain the confidence of the people, who were naturally more interested in relief of their suffering than in surveys.

Finally, the speaker summed up his impression of the feeling in France toward the Nazis, the English and the Americans. Apparently the majority of the population is grateful for the assistance of America, intensely hates the Nazis, and is willing to become allied with any enemy of theirs.

Dr. W. D. Robinson, who was on a similar mission to Madrid, compared his observations with those of Dr. Stuart. In Spain, the deprivation has been going on for a longer time, and reconstruction has been hindered by the persistence of intense lack of unity. Rations are about as in France, but an active bootleg trade alleviates matters somewhat, at least for the financially fortunate, and a great deal more food can be obtained from the United States, where there is only one border to be crossed. The native diet was found particularly inadequate in calories, protein, calcium and vitamin B. Vitamins A and C levels were adequate during the summer months when the survey was made, for at that time there were sufficient green vegetables. Although little classic deficiency disease was encountered, the children were definitely retarded, and conditions were reported worse in southern Spain. The nutritional outlook is dismal, for the grain crops do not appear promising, the Spanish government is trying unsuccessfully to be self-sufficient, and the relief agencies are being continually thwarted by the administration.

In reply to a question whether food was entering unoccupied France from the Nazis as a result of their collaboration pact, Dr. Stuart stated that exactly the opposite was taking place. Furthermore, the 100,000 prisoners returned to France as part of the same agreement were the physical and mental derelicts who were merely a burden to Germany and less than no help to the disil-

lusioned French people. In conclusion, Dr. Stuart pointed out that the most pressing immediate problem is an emotional rather than a nutritional one, but that the real work in the nutritional field is the surest way of building up the necessary morale.

#### BOSTON LYING-IN HOSPITAL JOURNAL CLUB

At a regular meeting of the Boston Lying-in Hospital Journal Club held at the hospital on October 30, Dr. Norris Vaux, of Philadelphia, spoke on "Some Local Uses of Estrogenic Hormones in Obstetrics and Gynecology."

This method of therapy was undertaken for several reasons. In the first place, in certain conditions and patients, the local tissues respond poorly if at all to parenteral injection of these hormones. Furthermore, the local application of the effective hormone has the advantages of easier use, a better concentration, a prompt effect and less systemic reaction. The conditions in which this mode of therapy has found favor include gonococcal vulvovaginitis in children, postmenopausal atrophic vaginitis, and hypoplastic and aplastic breasts and vulvas in young women.

In general, in the vaginal cases, a highly aqueous, acid solution of one of the estrogenic hormones is used. Besides the well-known increase of cornification of the vaginal mucosa, this increase of acidity adds another beneficial factor. Other forms of application have been suppositories and jellies with pH 4. In certain cases, mild antiseptics are added to the liquid or other medium and are thought to have certain definite advantages. It is actually a combination of two recognized forms of treatment. The antiseptic serves to control temporarily the sepsis until the hormone is effective. Smaller dosages of the hormone then become effective, which is a particularly important consideration in immature girls, in whom larger doses might cause premature development or unpleasant symptoms. Finally, it has been demonstrated that the inclusion of antiseptics does not inhibit the action of the hormones.

This form of therapy has been employed in the rather unusual syndrome of atrophic vaginitis in young adult women, in which the vaginal mucous membrane is thin, shiny and often ulcerated. Bacteriologic studies reveal mixed flora, and the persistent discharge is invariably found to be alkaline. The epithelial cells contain no glycogen. The menstrual cycle is usually only slightly disturbed, whereas the urinary estrogen values are more or less normal. As might be expected from these observations, the vaginal mucous membrane responds only to large doses of hormone. The use of 5-mg. suppositories of stilbestrol brought about clinical improvement, without any change of the menses but with noticeable changes of the vaginal mucous membrane. Withdrawal of the hormone caused an exacerbation of all symptoms and seems to indicate that continuous treatment is necessary to alleviate the symptoms.

In cases of pruritus vulvae and kraurosis, enormous doses were necessary to procure the desired effect. For this purpose, stilbestrol in oily form was dissolved in a vanishing-cream base, with from 10 to 100 mg. of the hormone to the 30 cc. of cream. About 4 gm. of this preparation was then daily applied to the affected area.

Certain cases of atrophic breasts have been found to respond to local therapy when other methods have failed. Here again stilbestrol in a vanishing-cream base has proved the most convenient and effective form of treatment. The addition of equal amounts of testosterone

as it displaces lipids and thus protects the liver stores. It was found that the most satisfactory means of obtaining these protein levels was by forced feeding, and that voluntary feeding, in addition to the parenteral use of glucose, was far superior to the latter alone. The most suitable protein so far found is casein, which is abundant in cottage cheese. Also used are Casec and protein digests, but the widely advertised gelatin is far inferior. That the additional protein must be suitable was demonstrated by feeding beef heart to animals and thereby actually increasing rather than decreasing the lipid content. If only the parenteral route is available, glucose and plasma are most effective, but nothing has been found to equal oral feedings. Despite already existing liver damage, every patient can be improved preoperatively by an adequate diet.

The indications for common-duct exploration are essentially those in common usage, but it is believed that this procedure should be carried out oftener. When such an operation is properly performed in competent hands, the mortality should not be materially higher than in the simple operation. Postoperatively, however, the draining bile should not be wasted even if the bile-salt concentration is low, for it is in this way that asthenic states develop, probably because of the extrahepatic importance of bile. A simple method for overcoming this difficulty is to connect a drainage bottle at the same height as the duodenum and thus cause the bile to flow into the gastrointestinal tract.

Postoperatively, the diet also plays a significant role, and the same principles apply as in the preoperative management. The best regimen is still unknown, but protein is certainly necessary. Carbohydrate aids only so far as it allows endogenous protein to be freed for use in regeneration of liver. In dogs, the best regeneration was noted when the protein fed contained 25 per cent liver.

Vitamin K therapy should be resumed postoperatively and continued until wound healing is assured. The blood values may and probably do fall after operation, so that preoperative values are not significant. Patients who fail to respond to such therapy before operation will not respond afterward, and should therefore receive blood or plasma. The T tube is never removed until a cholangiogram has been carried out, for even the best surgeons have been known to overlook a stone at operation. The mortality in common-duct explorations at Dr. Ravdin's clinic has decreased from 22 per cent in 1922-1929 to 11 per cent in 1935-1938, and to 2.6 per cent in 1938-1941. In the last 629 consecutive nonjaundiced patients operated on, there has been only one death, and this includes all types of biliary surgery.

The discussion was opened by Dr. Charles G. Mixter, of the Beth Israel Hospital. He favors cholangiography on the operating table at the time of operation. The closed method consists in inserting dye into the common duct through a ureteral catheter in the cystic duct, without opening the former. This is employed in questionable cases of small stones and apparently normal ducts, for common-duct exploration is believed to increase the morbidity and also the mortality in any but the most competent hands. The second type of cholangiogram is that taken through the T tube following exploration but before the patient leaves the table. Eighty-five of 88 cases of the latter type were satisfactory, and 75 came out as expected. Six residual stones were found, but in only 3 cases were they removed; the patient's condition did not warrant removal in the others. The type of patient that affords the greatest problem at present is the one with residual symptoms following operation and with a normal common duct. Some patients with so-called "dyskinesia" find relief from antispasmodics, but those with severe

usually not relieved. Dorsal sympathectomy, including the splanchnic nerves, offers some promise in such case but the series is as yet too small to draw any conclusions.

Dr. Chester M. Jones, of the Massachusetts General Hospital, emphasized the value of clinical evaluation for diagnostic purposes, but stated that liver-function tests have a place in following the progress of certain cases. On the whole, medical cases differ from surgical ones in that there are fewer cells for regeneration. Cases were cited in which surgery is eventually necessary but is contraindicated at the onset. Since jaundice in the presence of stones usually indicates poor liver function and since the stones may not be the cause of the jaundice, the patient should not be approached surgically so long as bile is reaching the gastrointestinal tract. Patients with high dye retention and slight jaundice are also poor risks, and liver tests are of some value in such cases. The diabetes associated with biliary-tract disease is invariably mild, and the removal of a diseased gall bladder and stones makes it even more so. Dr. Jones believes that the greatest risk in cardiac patients with biliary disease is leaving them alone. Esophageal hernia may give rise to similar stimuli, which are probably afferent to the heart without passing through the splanchnic nerves. Vitamin K may be used as a measure of liver insufficiency and often fails to cure or aid medical cases. It is now known that whole blood, but not pooled, contains prothrombin and thus aids in establishing normal levels.

## BOOK REVIEW

*Oral Pathology: A histological, roentgenological, and clinical study of the diseases of the teeth, jaws, and mouth*. By Kurt H. Thoma, D.M.D., and Charles A. Brackett, D.M.D. 4°, cloth, 1306 pp., with 1370 illustrations, including 137 in color. St. Louis: The C. V. Mosby Company, 1941. \$15.00.

Although the title of this work suggests a study of the pathologic findings in oral disease, it also represents a clinical study of disease of the teeth, jaws and buccal mucosa, with radiographic findings and excellent histologic illustrations.

The forty-five chapters include studies of hereditary, hormonal and nutritional influences in the development of the teeth and jaws, together with experimental pathology. In the latter subject, there has been the greatest progress in the study of oral disease in recent years. A review of the subject of dental caries based on an enormous literature is presented, with extracts from the more important articles and with a special reference to experimental work. The chapter on periodontal disease, with modern classification of the many lesions, helps to simplify the terminology of the subject. Diseases and tumors of the jaw are dealt with in a manner similar to that in a previous book, *Clinical Pathology of the Jaws*, published a few years ago. Chapters on diseases of the oral mucosa, lips, tongue and salivary glands are especially well illustrated in color.

The bibliography, which is very complete and up to date, includes the important articles in the foreign literature.

This volume is the most complete of its kind in the American literature, and its compilation is a result of many years of study of oral disease on the part of the authors. Disease of the oral cavity has been a neglected field in medicine, and this work should be of equal interest to the medical clinician, the oral surgeon and the clinical dentist. A knowledge of oral disease is valuable to both the medical and the dental practitioner, since the oral cavity may be considered the mirror that reflects the presence of disease elsewhere in the body.

## THE TREATMENT OF MAMMARY PAIN AND SECRETION WITH TESTOSTERONE PROPIONATE\*

IRA T. NATHANSON, M.D.,† JOE V. MEIGS, M.D.,‡ AND LANGDON PARSONS, M.D.§

BOSTON

CERTAIN syndromes in women before the menopause are characterized by mammary swelling and pain, with or without secretion from the nipple. They are undoubtedly present in a large percentage of cases, but may vary considerably in their intensity and extent. Many women have obvious changes in the breasts and may never be aware of any abnormality until it is found on routine examination, whereas others with minimal changes may have marked subjective manifestations. Hence, it is sometimes extremely difficult to distinguish the syndrome from what is considered a normal variation. Only patients with pronounced lesions seek consultation with a physician, either for relief of symptoms or because of fear of cancer. These patients, who have unequivocal signs and symptoms, are discussed in this paper.

The lesions are generally classified under the generic term of "chronic cystic mastitis," but should be grouped under more specific terms because they represent fairly distinct clinical and pathologic entities. The changes are believed by most observers to be due to a sex-hormone imbalance whose nature is not clear. Treatment of these syndromes with estrogenic hormone on the assumption of an estrogen deficiency was first suggested by Cutler.<sup>1</sup> Others have since reported varying success from treatment with more active preparations of the same hormone. It is the purpose of this communication to record our experience in the treatment of these lesions by the use of the male sex hormone, testosterone. The rationale of therapy with testosterone is based pri-

marily on experimental data in animals, which suggest that relatively prolonged administration of the hormone not only reduces the secretory activity but also may reduce the number of cells of the breast epithelium, especially those in a hyperplastic process. Further evidence suggests that an action on the vascular bed of the breasts may relieve the venous congestion and edema so often seen in these patients. It is our belief that excess secretion, increased vascularity and edema are usually responsible for the swelling and pain, and that the symptoms and signs abate only after resorption of the fluid or a diminution in the venous engorgement. Therefore, testosterone, because of its action, should be effective in the treatment of these syndromes.

A thorough clinical and experimental study has been carried out for the last six years in the cases reported below, which were selected from a much larger group. Several of our observations have been recorded,<sup>2</sup> and others, particularly those concerned with the mechanisms of the syndromes, will be published soon. In the evaluation of any type of therapy in these lesions, it is imperative to select the patients with care so that an accurate clinical appraisal of the results can be made. Cases were therefore chosen on one or more of the following criteria: frequent examination without treatment by the same examiner for a long time, so that the possibility of a psychogenic element or a spontaneous remission (both of which are not uncommon) could be minimized; severity of the syndrome and presence of unquestionable physical findings, such as marked nodularity and secretion, so that any change would easily be recognized; failure to control the symptoms with a suitable breast support or with a placebo, or after estrogenic therapy; absence of demonstrable pelvic disease or removal of such disease without re-

lief of symptoms, since these processes are frequently related; intelligence of the patient, so that reasonably reliable information about the subjective symptoms would be available.

### CLASSIFICATION OF LESIONS

We distinguish two main groups—adenofibrosis and nonpuerperal mammary secretion—with

the first group, the symptoms may abate at the menses. The discharge may be serous or may resemble colostrum, and may be of varying degrees of viscosity. Examination usually reveals dilatation of the ducts, especially near the areola, and slight nodularity elsewhere in the breast. The breast tissue itself is ill-defined, and the nipples are frequently crusted. If secretion is not obvious,

TABLE 1. *Incidence of Symptoms and Physical Findings.*

SYMPTOM	TOTAL NO. OF CASES	CASES WITH SYMPTOMS			CASES WITH PHYSICAL FINDINGS		
		PAIN	SWELLING	SECRETION	DILATATION OR NODULARITY OF DILATED DUCTS	SECRETION	
Adenofibrosis . . . . .	9	9	7	0	7	9	0
Nonpuerperal mammary secretion . . . . .	21	10	15	5	10	21	21

various gradations and do not include obvious cystic disease or isolated lumps or nodules (Table 1).

*Adenofibrosis.* The patients in this group have cyclic swelling and pain in the breast, usually in the premenstruum, but without obvious or demonstrable secretion. The relief that usually ensues with the onset of the menses is dramatic. On examination, two extreme types are distinguishable, but many present intermediate variations.

*Type I.* There is an increase in density of the entire mammary gland, which is well differentiated from the overlying skin, the subcutaneous tissues and the underlying structures. The gland is firm, and usually resembles a saucer or disk in its configuration. These changes as seen in histologic sections are due to an increase in the stroma, without obvious changes in the ducts or acini. During the premenstruum, there is frequently venous engorgement, as well as edema.

*Type II.* This resembles the first type, especially in the density of the gland. In addition, there is a diffuse, fine or moderate nodularity throughout the breast but usually most prominent in the upper outer quadrant. Histologically, there is an increase in the number of acini, as well as an increase in the fibrous tissue, with the usual edema.

Either of the types may show hyperplasia and, sometimes, dilatation and secretion within the acini. Semb<sup>3</sup> has referred to these entities as adenofibrosis, and Dawson<sup>4</sup> as adenositis. Taylor and Waltman,<sup>5</sup> in a detailed study, have recently presented an excellent description of these syndromes.

*Nonpuerperal mammary secretion.* The salient feature of this type is discharge, usually accentuated before the menses and sometimes associated with swelling and cyclic or acyclic pain. As in

removal of the crust, with gentle pressure on the ducts, results in the escape of fluid from the nipple. On gross and microscopic examination, the ducts are dilated and contain secretion and, sometimes, inspissated material. Hyperplasia of the duct and acinar epithelium, with edema in the supporting tissue, is evident. We have termed this the nonpuerperal secretory type of breast, a designation also utilized by Taylor and Waltman.<sup>5</sup> This group probably falls into the type designated as mazoplasia by Cheate and Cutler<sup>6</sup> and epitheliosis by Dawson.<sup>4</sup>

Many of the cases include features of both the above groups, and may be placed in a third class. However, for the purpose of clarity in this communication, the lesions have not been classified further. All cases with secretion are placed in the first group, in spite of the fact that they may show some of the manifestations of the second.

### METHOD OF TREATMENT

The chief preparation used was testosterone propionate.\* In a few cases, testosterone made up in a lanolin base was utilized as an ointment. Ten mg. of testosterone propionate in 1 cc. of sesame oil was given intramuscularly every other day, beginning about two weeks prior to the expected period. If the symptoms were of long duration during the cycle, treatment was started at least a few days before the onset of the expected symptoms and continued up to the period. In the more intractable cases, the hormone was given every other day throughout the cycle, except during the period of flow. At times, the dose level was increased to 25 mg. In any event, the maximum amount given during any single month was 250 mg., but the usual dosage varied between 75

\*We are indebted to Drs. Gregory Stragnell and Max Gilbert of the Schering Corporation, Bloomfield, New Jersey, and to Dr. Ernst Oppenheimer of the Ciba Pharmaceutical Products, Incorporated, Summit, New Jersey, for generous quantities of testosterone propionate supplied under the trade names of "Oreton" and "Perandren."

and 150 mg. If the hormone was administered percutaneously in the form of the ointment, the patient was instructed to rub the equivalent of 2 to 4 mg. into the skin of each breast before retiring. The total dosage was therefore 28 to 56 mg. a week. Although the amount used by injection was approximately the same as that given intramuscularly, the relative effect of each route is probably different. The percutaneous method, as contrasted to parenteral administration, aims at a more direct action on the breast, with less systemic effect. Since the exact mechanism of action of the hormone on the breast is in doubt, it is not known at present if any one method is to be preferred. However, Salmon et al.<sup>7</sup> are of the opinion that testosterone if properly used is equally effective by any route. In this series, injection was reserved for patients who could not report regularly for injections.

Treatment was never continued for more than three consecutive months in any given case without a rest period of one to several months before resumption. When the larger dosages were used, the maximum length of any single period of treatment was two months. The importance of these rest intervals is pointed out below. It was seldom necessary to give more than two courses of therapy to evaluate the results.

#### COMPLICATIONS OF TREATMENT

Overdosage with testosterone in women produces undesirable side effects, such as hirsutism, enlargement of the larynx with deepening of the voice, acne and enlargement of the clitoris. With the dosage used in our series, 2 patients developed mild hirsutism, and 1 developed moderately severe acne. These effects regressed rather rapidly when treatment was discontinued. It is for this reason that we do not continue treatment too long. We are of the opinion that prolongation of the treatment rather than the dose level is the significant factor in the production of undesirable side effects. As much can probably be accomplished by a definite routine of treatment of two or three months, followed by a rest period for a month or more before resuming the medication to allow for partial regression of the undesirable effects of the hormone. It seems likely that each course of treatment will produce some regression of the breast lesions and that if the interval without treatment is not too prolonged, recurrence will not reach the pretreatment state. In this way, the drug can be used more safely and probably as effectively. It should be emphasized that the hormones available at present are potent, and that a safe dosage for one person may be excessive for

another, because of individual susceptibilities and responses. To avoid the side effects, one should treat each patient with these factors in mind. It is extremely interesting, however, that treatment did not alter ovarian function, since 2 patients in this group subsequently became pregnant, delivered normal babies and had normal lactation. Furthermore, with the dosage used, no effect on the menstrual cycle, with the exception of an occasional delay for a week, was noted in any case. Larger dosages would undoubtedly have caused a temporary suppression of the menses in some patients.

#### RESULTS

The treatment of these syndromes with testosterone was first suggested by Desmarest and Capitan,<sup>8</sup> who reported favorable results in 16 of 17 treated cases. They concluded that the hormone suppressed the congestion preceding the menses, decreased or inhibited the development of further disease, and caused regression of the nodules. Others<sup>9-11</sup> later published similar observations. Spence<sup>10</sup> and Atkins<sup>11</sup> stressed the psychogenic element in certain patients who present themselves with mammary pain. The former injected olive oil in 24 patients, 13 of whom had "dramatic relief." The latter, in a series of 212 patients, found that 31 had relief after the administration of inert pills or the injection of oil. He stated that these patients must have consisted largely of those in whom a psychologic factor predominated, although some undoubtedly had a spontaneous remission. However, 16 patients in Spence's series were considered to have a definite indication for treatment. Ten of 12 with pain were improved or completely relieved, and 8 of 12 with nodularity showed regression after treatment with testosterone. Atkins selected 34 patients as suitable for treatment, and 25 of these showed improvement. The degree of regression of symptoms and signs paralleled the total dosage and the period during which treatment was employed. Atkins concluded, however, that much of the beneficial effect on the breast was vitiated by a fairly high percentage of undesirable side effects. Geist et al.,<sup>7</sup> in a recent publication, noted improvement in 6 of 10 patients with premenstrual pain and in 2 of 4 patients with cystic nodular breasts.

It can be seen from Tables 2 and 3 that in our series testosterone propionate was effective in the treatment of mammary pain and secretion. All the patients with adenofibrosis were improved or completely relieved of their symptoms. In 7, an improvement in the physical findings was beyond any question. Of 21 patients with mammary se-

cretion, 18 were subjectively improved or completely relieved. It is interesting that secretion was completely inhibited during the period of treatment in 13 patients.

The results of therapy with testosterone seem significant, since 11 of the entire group had been previously treated, without success, by estrogenic hormone, and the remainder had had a placebo either orally or by injection, or fell into one or more of the criteria outlined above. This, therefore, in spite of obvious physical findings, further

eliminated patients who might possibly have had a neurosis or spontaneous remission. Consequently, these observations are in accord with those of other investigators.

The most obvious clinical change after treatment was a reduction or inhibition or premenstrual swelling that was easily observed by the patient and the examiner, even though gross secretion or localized areas of tenderness and pain persisted.

TABLE 3. *Results of Testosterone Therapy in 21 Patients with Nonpuerperal Mammary Secretion.\**

THERAPEUTIC RESULT	REGARDING SYMPTOMS	REGARDING PHYSICAL SIGNS	REGARDING SECRETION
Complete relief	12	3	13
Improvement	6	15	5
No change	3	3	3

\*Of 8 patients treated unsuccessfully with estrogens, all but 2 had complete relief or improvement in symptoms and physical findings.

Although there was complete relief from symptoms or secretion, in many cases the physical signs improved but did not disappear completely. This improvement was manifested by softening, a decrease in nodularity and even a reduction in the size of the breast. When not completely inhibited, the secretion was reduced or exhibited gross alterations. Many patients volunteered the information that it was necessary to use a smaller brassière. We consider this to be an important observation in the evaluation of the therapy, since it signifies that the major symptoms had been relieved.

Recurrence of symptoms and physical signs was the rule after treatment was discontinued. Few patients had relief after six months, and many

had recurrence within the first few months after treatment was stopped. However, with recurrences, the symptoms were usually less severe, and the findings were not so pronounced as they had been in the pretreatment period. Some of the patients were given further courses of treatment, with satisfactory results, but to date few have continued to remain completely free of symptoms. Therapy of a more rigorous nature for longer periods might have given permanent relief. It is questionable, however, whether one would be justified in such an attempt, because of possible undesirable generalized or local side effects. As stated above, regardless of individual idiosyncrasies, these effects are usually in proportion to the amount and the period over which the hormone is given. It is our opinion that proper administration of the hormone can produce the desired therapeutic result without reaching the threshold for other manifestations. This has been well demonstrated by Geist and Salmon,<sup>12</sup> who made careful observations on a large series of patients treated with testosterone for various endocrine disturbances. In our series, except in a few cases, the dosage and time interval appeared to be below the threshold level for the production of undesirable changes. In this respect, therefore, our findings differ from those of Spence<sup>10</sup> and Atkins,<sup>11</sup> who usually employed large amounts of the hormone for a longer time.

It can be demonstrated histologically that testosterone is capable of reducing the number of cells and the activity of the epithelium in the breasts of animals<sup>13</sup> and, to a lesser extent, in human beings.<sup>11</sup> The mechanism by which the clinical and laboratory changes are produced is not clear. It is commonly recognized that the estrogenic hormone, if not properly balanced, results in hyperplasia of the breast epithelium. However, it has not been established whether this is a direct effect or one that is mediated through the anterior hypophysis, presumably by increasing the activity of the mammogenic hormone, which is believed by many to be the stimulating factor in epithelial growth in the breast. Another hormone of the anterior hypophysis—prolactin—is probably responsible for secretion and lactation. In experimental animals and in human beings, it has been shown that testosterone may counteract the action of the estrogens. It may also inhibit secretion and lactation, probably by preventing the activity of prolactin on the breast itself, or through its action on the pituitary gland. Therefore, since it is probable that these mammary dyscrasias are due to a hormonal imbalance, it seems likely that the beneficial effects of testosterone may be ac-

complished by establishing a balance or by counteracting the action of the other hormones that are probably involved in the process. This balance in itself may result in an alteration of the vascular bed of the breast, which in turn may be the sole factor in the reduction of venous congestion, edema, epithelial elements and secretion. At present, it is difficult to say whether these effects of testosterone are due to a direct action on the breast or to an indirect one mediated through other organs.

Finally, it should be stressed that this treatment must be reserved for patients in whom there is not the slightest doubt concerning the presence of cancer, or any evidence of an isolated tumor, or bleeding from the nipple.

### SUMMARY AND CONCLUSIONS

Testosterone propionate was administered to 30 carefully selected patients with severe mammary pain and secretion. It was found to be an effective agent in the relief of the syndromes in a high percentage of cases. It appears to be more efficacious than the estrogenic hormone in the treatment of the same lesions. Recurrence of symptoms and signs is the rule, usually within six months

after medication is discontinued. Prolonged and continuous treatment, especially with large doses, is to be discouraged. As much as can be accomplished by planned periods of treatment followed by adequate rest intervals. Many patients present a predominant psychogenic element, and others have spontaneous remissions, therefore, care should prevail in the selection of the case for this or any similar type of therapy.

## A COMPARISON OF BLOOD PROTHROMBIN LEVELS WITH STANDARD FUNCTION TESTS IN DISEASES OF THE LIVER

FRANKLIN W WHITE, MD,<sup>1</sup> ENRIQUEL DEUTSCH, MD,<sup>2</sup> and STEPHEN MADDOCK, MD.<sup>3</sup>

BOSTON

IN 1935, Quick<sup>1</sup> introduced a simple interpolative method for measuring the amount of prothrombin in the blood. This proved an invaluable guide in the indications for treatment of vitamin K deficiency. The experimental work associated with the discovery of vitamin K<sup>2,3</sup> suggested that the liver was important in prothrombin production. When it was found that persons with a damaged liver often responded poorly to vitamin K treatment,<sup>4-7</sup> efforts were made to expand the use of the prothrombin test to the status of a liver-function test.

A possible correlation between prothrombin and liver function tests has been suggested by early reports.<sup>8,12</sup> In 1939, Wilson<sup>8</sup> remarked

The quantitative level of the plasma prothrombin was found to correlate closely with the quantity of hippuric acid excreted . . . [and that] the quantitative levels of plasma prothrombin and the amount of hippuric acid excreted following the ingestion of a known quantity of sodium benzoate would seem to have reflected most sensitively and consistently the degree of liver damage existing.

Stewart and Rourke,<sup>9</sup> in 1939, suggested that further study might reveal that the prothrombin depression is a better index of liver damage than other standard liver function tests.

Pohle and Stewart,<sup>10</sup> in 1940, observed, "The present studies suggest that in the absence of obstructive jaundice, external biliary fistula or an abnormal intestinal absorptive surface, the plasma prothrombin concentration serves as a measure of liver function."

Andrus,<sup>12</sup> in 1941, considered one of the most fruitful fields of the study of vitamin K to concern its use in the investigation of liver function;

<sup>1</sup>Read at the fifty-sixth annual meeting of the Association of American Physicians, Atlantic City, May 6, 1941.

<sup>2</sup>From the Second and Fourth (Harvard) Medical Services and the Surgical Research Laboratory, Boston City Hospital.

<sup>3</sup>Consulting physician, Boston City Hospital.

<sup>4</sup>Fellow in surgical research, Boston City Hospital.

<sup>5</sup>Director of surgical research, Boston City Hospital.

he believes that such a test "possesses certain advantages over even the best of the current tests of liver function."

On the other hand, two recent papers<sup>13, 14</sup> have shown little or no correlation between the hippuric acid excretion test and blood prothrombin levels either before or after the administration of vitamin K in adequate doses. Because of these discrepancies, it seems worth while to present the results in a series of cases of liver disease encountered as routine diagnostic problems on the wards of a large hospital, without reference to the type of disease presented, and to compare the results in an impersonal way.

The material consists of 100 unselected cases of liver and biliary-tract disease in which about 700 tests were made. The prothrombin percentage and its response to vitamin K in adequate doses were compared with the excretion of hippuric acid and urobilinogen in the urine, and fractional bromsulfalein elimination from the blood. For the sake of simplicity, this paper is confined largely to a comparison of the prothrombin level with the hippuric acid excretion.

#### METHODS

Hippuric acid excretion in the urine was determined, following oral administration, by the gravimetric method of Quick.<sup>15</sup> The prothrombin time was measured by the Quick<sup>1</sup> technic, and converted to the percentage of normal blood prothrombin by reference to a curve obtained according to the method of Kark and Lozner.<sup>16</sup> The hippuric acid excretion test was usually performed on the day that the blood prothrombin level was estimated or within three days (seventy-two hours) of that time.

The urobilinogen in the urine was estimated by the Wallace and Diamond procedure,<sup>17</sup> and the bromsulfalein retention by a fractional method,<sup>18</sup> using 2 mg. of bromsulfalein and testing the blood at the end of five and fifteen minutes. Some of the various tests were repeated four or five times in all cases and, in some cases, up to ten and twenty times.

The preparations employed for restoring vitamin K were either 2-methyl-1,4-naphthoquinone, in 1-mg. doses orally each day or 3.2-mg. doses of 2-methyl-1,4-naphthoquinone-3-sodium sulfonate intramuscularly once in four or five days. Patients with high or normal blood prothrombin levels were not given vitamin K preparations. All patients received the currently accepted treatment for liver damage—that is, a high-carbohydrate, normal-protein and low-fat diet, and oral or intravenous glucose solutions, thiamin and nicotinic

acid fortified with other vitamins and occasionally reinforced with parenteral liver extract.

#### RESULTS

##### *Correlation of Tests*

A definite lack of correlation between the prothrombin level and hippuric acid excretion was found in a large number of cases (Table 1). Hippuric acid excretion was often much below the normal level of 3 gm., whereas the prothrombin level varied from low to normal in different cases.

There are two ways of using the prothrombin level as a clinical test: either as an index of vitamin K deficiency on admission or as one of response to vitamin K treatment on the part of the patient. The second is much more valuable, since the variable factor, the amount of vitamin K available, is removed. The prothrombin levels on admission may be within the same range, but the response to vitamin K treatment best brings out the differences that are found in various types of liver disease.

##### *Discovery of Liver Damage*

In the severest type of liver damage (acute diffuse necrosis), all the recognized liver-function tests used were found to be positive. In cases of intermediate severity, such as the cirrhoses, these tests varied greatly in the proportion of cases giving a positive response. In our previous experience<sup>18-20</sup> and in the present examination of this group of cases, the percentage of initial abnormal tests in cirrhosis is approximately as follows: oral galactose tolerance, 25 per cent; cholesterol ester, 45 per cent; prothrombin, 53 per cent; urobilinogen in the urine, 77 per cent; hippuric acid excretion, 88 per cent; and fractional bromsulfalein excretion, 91 per cent. The prothrombin time holds an intermediate position as an index of liver damage. In the milder types of hepatic dysfunction, some tests were always negative, but others, such as the hippuric acid excretion and the fractional bromsulfalein elimination, were positive in nearly all cases. The prothrombin level was normal in 47 cases in this series at the time of admission, and below normal in 53 cases. Pohle and Stewart<sup>10</sup> found 47 per cent below normal in a similar group of 136 cases.

Table 2 lists the total number of cases with abnormal prothrombin levels before and after treatment. In 53 cases, the prothrombin level was abnormal on admission; the hippuric acid excretion was abnormal in 83 cases. In cases of acute hepatitis, a low prothrombin level quite often returns to normal after active glucose and fluid therapy without giving vitamin K analogues (Table 1. Cases 24, 58 and 59).

\*Watson test

†After three weeks

‡After two weeks

The prothrombin level remained below normal after treatment in 35 cases. Twenty-five were cases of chronic hepatitis, and 1 was a case of common-duct stone with biliary cirrhosis. In 5 cases of acute hepatitis, 3 patients died, and 2 made slow recoveries. There was 1 case of cancer of the liver, 3 of obstructive jaundice due to cancer of

\*In 8 cases, no oral hippuric acid test could be performed.

the head of the pancreas, and 1 of cholecystitis, with postoperative bronchopneumonia and abscess of the lung.

### Diagnosis

Table 1 shows all the cases in which the initial prothrombin level was below normal. The initial prothrombin values and those found after three or four days of treatment with vitamin K are given, as well as the net change in the prothrombin level during that period. The initial prothrombin level was similar in the three groups,—obstructive jaundice, acute hepatitis and chronic hepatitis,—but the response to treatment with vitamin K was very different.

In the obstructive cases, the initial prothrombin level was below normal in 8 of 14 cases and, as a rule, rose quickly to normal in one to three days. In the cases of acute hepatitis, the prothrombin level rose rapidly to normal in the majority of cases, possibly because the tests were made at the time recovery began. In 2 fatal cases (Cases 14 and 88), the prothrombin level fell. In 1 (Case 17), the prothrombin fell at first and slowly returned to normal. In 1 (Case 87) of acute liver necrosis due to carbon tetrachloride poisoning, the prothrombin gradually rose to normal, but the patient died later of septicemia with metastatic abscesses.

The 27 cases of chronic hepatitis with an initial low prothrombin level behaved quite differently from those in the other two groups. After treatment, there was a well-marked rise in only 2 or 3 cases; in 13, there was a slight rise; in 5, there was no change; and in 6, 4 of which were fatal, the level fell. In most of these cases, the prothrombin remained at a distinctly low level of about 40 to 50 per cent after vitamin K therapy, which is quite un-

like the first two groups, in which the level rose to normal except in a small percentage of cases (Table 1).

### Correlation of Visible Bleeding with Prothrombin Levels

In the whole group, there were 6 cases of visible bleeding associated with low prothrombin levels (5, 20, 23, 27, 30 and 35 per cent): 1 case of bleeding from the nose and gums, 2 of ecchymosis, 1 of hematuria, 1 of hematuria and bleeding from the nose and gums, and 1 of hemoptysis. Pohle and Stewart<sup>10</sup> found 10 such cases (7 per cent) among 136 cases of liver and biliary-tract disease.

It is interesting to note that there were 15 other cases with low prothrombin levels (10, 15, 16, 23, 24, 27, 28, 29, 29, 30, 30, 30, 31, 32 and 35 per cent) and no visible bleeding. Pohle and Stewart found 15 such cases (11 per cent) in their group of 136 cases.

There were 8 other cases of bleeding with normal prothrombin levels; 4 cases of gross hematemesis, 1 of melena that was probably due to varices in cirrhosis, 2 of epistaxis, and 1 of melena with cancer of the rectum.

### COMMENT

*Methods.* The variation in methods for performing the hippuric acid excretion test by the gravimetric method may account for the different normal values cited by various authors. Our experience and that of Snell and McGith<sup>21</sup> and of Quick<sup>15</sup> show that the greatest number of normal tests with the method used have ranged between 2.5 and 3.5 gm., with occasional values at 4 and 5 gm. When hippuric acid crystals in the urine are subjected to the additional procedure of salting out, as suggested by Weichselbaum and Probst<sup>22</sup> and later by Quick,<sup>23</sup> the majority of normal values fall in the higher range.

A confusing factor in prothrombin determination is due to the fact that some workers use the initial prothrombin percentage and others the response to vitamin K analogues. The latter seems to be the better criterion, since the variable factor of adequate vitamin K is ruled out. Moreover, the initial figures do not have any possible differential value.

After performing a large number of prothrombin tests and correlating them with clinical observations, we considered a value of 80 to 100 per cent to be within normal limits. When the time of the unknown was shorter than the normal control, the value was recorded as 100 per cent.

Acetone extracts of whole rabbit brain, even in dilution, gave no constant value that could be du-

plicated and therefore were considered unsatisfactory.

Blood collected for this determination should not be allowed to stand for more than four hours, because fibrinogen is precipitated and is a definite source of error.

The curve shown in the paper by Kark and Lozner<sup>16</sup> was used in converting coagulation time to prothrombin per cent.

Dilution of the plasma for the prothrombin test may be a source of error.

**Correlation of tests.** It is obvious that the degree of correlation between the two tests is very poor, and that the prothrombin test does not discover the milder grades of liver damage but only those that are well marked. The prothrombin level was abnormal in only 53 per cent of the cases; it may be normal when liver damage is well marked and readily shown by other tests. This agrees with the work of DeLor and Reinhart<sup>24</sup> and of Lucia and Aggeler.<sup>14</sup>

**Prognosis.** The prognostic value of an increased prothrombin level after treatment is definite but limited in scope. In diseases of the liver after adequate treatment with vitamin K, several types of response occur. The prothrombin level may return to normal within twenty-four to forty-eight hours in some patients, or may rise gradually over a period of weeks. In other cases, it may fail to rise or may actually fall despite adequate therapy. In cases in which after vitamin K treatment the prothrombin level rises only a little, fails to rise or falls, the prognosis is progressively poorer. A falling prothrombin level with adequate vitamin K therapy usually means irreversible damage to the liver and corresponds quite well with low hippuric acid test values. All 4 patients in whom this occurred died within a short time.

On the other hand, in the cases in which the prothrombin percentage returns to normal, the test is a much less accurate guide in prognosis than the hippuric acid excretion, since the prothrombin level may become normal or approximately normal in the presence of serious disease of the liver. Four patients—2 with cancer of the liver, 1 with cancer of the pancreas, and 1 with acute hepatitis with multiple abscesses—died within a week after normal prothrombin determination. The hippuric acid test was very low in all. This is entirely in agreement with Quick's<sup>25</sup> recent statement that good liver function and a low prothrombin level are better from the patient's point of view than poor liver function and a high prothrombin level.

In estimating the risk at operation in diseases of the liver and biliary passages, the prothrombin

level is the best guide to the presence of a bleeding tendency, but the hippuric acid excretion has proved much better than the prothrombin percentage in revealing general hepatic insufficiency.

In cirrhosis, the prothrombin level may not respond well to treatment, but the percentage of normal prothrombin can be kept well above the bleeding level. Bleeding in the hepatic cirrhoses

FIGURE 1. Early Prothrombin Response to Vitamin K Treatment in 20 Cases.

was about as often due to ruptured varices as to a low prothrombin level in our experience.

In one patient with cirrhosis, the prothrombin percentage remained low after injections of naphthoquinone derivatives, and a poor prognosis was given, but proved to be an error. When this patient was seen a year later, after much restriction in the use of alcohol and a more normal diet, the prothrombin level was found to be 100 per cent of normal, but the hippuric acid and brom-sulfalein excretion was definitely diminished.

In short, in response to vitamin K treatment in the patient with a relatively good liver function (early obstruction), or with a recovering liver (acute hepatitis), the prothrombin level returned rapidly to normal; with severe chronic damage (chronic hepatitis), the prothrombin level remained relatively low.

A small number of cases of acute hepatitis with low initial prothrombin percentage showed rapid increase to normal, after the use of increased amounts of glucose and fluids and without the aid of vitamin K analogues. It has been suggested that glucose plays a vital role in blood coagulation.<sup>26</sup>

**Fatal cases.** The prothrombin levels were low a few days to a week before death, in spite of ac-

tive treatment with vitamin K, in 7 cases with an acute element: 2 of acute hepatitis (prothrombin levels of 10 per cent), 4 of acute exacerbations in chronic hepatitis, and 1 of cholecystitis with an acute lung abscess (32, 40, 48, 48 and 53 per cent, respectively).

The prothrombin levels were low in 4 other cases tested one to two months before death: 2 of cardiac cirrhosis and 2 of portal cirrhosis (23, 33, 28 and 42 per cent, respectively).

The levels were high or normal within a week of death in 4 cases: 3 of cancer of the liver and 1 of cancer of the pancreas (70, 80, 98 and 100 respectively).

The levels were also high in 6 cases tested one month before death: 3 of cirrhosis, 1 of pylephlebitis and 2 of cancer of the liver (81, 90, 90, 95, 100 and 100, respectively).

In contrast to these results, the hippuric acid was always low or very low in fatal cases tested within a week of death (0.3, 0.3, 0.4, 0.7, 1.2, 1.3, 1.7 and 2.0 gm.), and was low in every fatal case but one (cardiac cirrhosis) tested one to two months before death (0.3, 0.4, 1.5, 1.7 and 2.0 gm.).

*Diagnosis.* The prothrombin level has some suggestive value in differential diagnosis of diseases of the liver, but the results must be interpreted with some degree of caution. One feature stands out: a prompt return to normal after vitamin K treatment has been found more commonly in obstructive jaundice than in some types of parenchymal damage, but a sharp distinction must be made between acute and chronic forms of the latter.

Andrus<sup>12</sup> has emphasized the value of prothrombin tests in the study of liver function. He states:

The [prothrombin] test finds one of its greatest fields of usefulness in distinguishing between jaundice of extrahepatic origin due, for example, to obstruction of the common duct by tumor or stone and that due to parenchymal liver disease. In brief, we have found that in the former, the plasma prothrombin either remains above 80 per cent or if it be depressed, rises following the intramuscular injection of 2-methyl-1, 4-naphthoquinone by more than 10 per cent in the first forty-eight to seventy-two hours. In intrahepatic jaundice the prothrombin, which here is uniformly depressed, either fails to rise by this amount or continues to fall.

In 40 jaundiced patients,—25 with common-duct obstruction and 15 with parenchymatous liver disease,—he found the test to be almost 100 per cent correct.

An effort was made to use this rapid type of response to vitamin K treatment as an aid in the diagnosis of obstructive jaundice. In 4 cases of

severe jaundice with acholic stools for a period of one or two weeks, in which the diagnosis of obstruction was seriously considered, there was an immediate rise to normal in the prothrombin level on vitamin K therapy; however, all these cases were proved to be acute parenchymatous hepatitis by an unmistakable course and subsequent history.

In our 14 cases of obstructive jaundice, there were 9 (64 per cent) with low initial prothrombin levels. The percentage of such cases has been higher in other reported series—Stewart and Rourke<sup>9</sup> found 80 per cent in 24 cases, and Pohle and Stewart<sup>27</sup> 87 per cent in 23 cases.

The presence or absence of urobilinogen in the urine and feces has proved to be the most valuable differential test between completely obstructive and parenchymatous jaundice. The hippuric acid and bromsulfalein tests have no differential diagnostic value, since they are positive in nearly every case of liver disease, regardless of its type.

#### SUMMARY

The blood prothrombin level and its response to vitamin K treatment were compared with standard liver-function tests, such as the hippuric acid and fractional bromsulfalein excretion, and the urobilinogen in the urine in a group of 100 cases of various diseases of the liver, and although of prime value in revealing vitamin K deficiency, was found to be of secondary importance as a liver-function test.

The degree of correlation between the prothrombin level and the liver-function tests used was very poor. The prothrombin test does not reveal the milder grades of liver damage but only those that are well marked. It was abnormal in only 53 per cent of the cases, and may be normal when liver damage is well marked and easily shown by the other tests.

The prothrombin level was less definite in prognosis than the liver-function tests used (with the single exception of discovery of a bleeding tendency). If normal, it may be misleading. An abnormal test is significant, and if a low prothrombin level rises but little, fails to rise or falls after vitamin K treatment, the prognosis is progressively unfavorable. In acute hepatitis, a falling prothrombin level in the presence of adequate vitamin K usually means irreversible, widespread liver damage.

In differential diagnosis of diseases of the liver the prothrombin level has only a suggestive and limited value. The sole diagnostic point noted is that the prothrombin percentage is much likelier to rise rapidly to normal after vitamin K treatment

in obstructive jaundice and healing acute hepatitis than in chronic hepatitis (cirrhotoses).

In some cases of acute hepatitis with low initial prothrombin levels, there has been a rapid response to active glucose and fluid intake comparable to that in similar cases treated with vitamin K.

Bleeding in the hepatic cirrhotoses was about as frequently due to ruptured varices as to a low prothrombin level.

The authors acknowledge their indebtedness to Dr Robert Kark, formerly research fellow in medicine, Harvard Medical School, for prothrombin data in some of the earlier cases, and to Miss Dorothy Jensen and Mr. William Appleby for technical assistance.

## FRACTURES AROUND THE ANKLE JOINT\*

WILLIAM DARRACH, M.D.†

NEW YORK CITY

ANY pain or interference with the function of the ankle joint is a real handicap, whether the patient is a longshoreman, a clerical worker or a playboy. Injuries to this part of the body can be handled more intelligently and more successfully if the details of anatomy, physiology and pathology are understood and the general principles applied in each case than if a fixed rule of procedure is followed blindly.

### Anatomy

The lower extremity of the tibia expands and becomes four sided. Its medial portion projects down as the medial malleolus. Articulating with the outer side is the expanded lower end of the fibula, which forms the lateral malleolus. The lower surface of the tibia is concave and articu-

lates with the upper surface of the talus, which is narrower behind than in front and is in close contact on either side with the articular surface of the malleoli. The lower tibia and the two malleoli are spoken of as the mortise of the ankle, the talus being the tenon. The stability of the ankle, and indeed of the whole foot and leg, depends a good deal on the strength and accurate fitting of this tenon and mortise. It allows free flexion and extension, but no lateral motion; inversion and eversion of the foot take place in the subtalar and midtarsal joints. These three bones are held firmly in place by strong ligaments, which are also essential to stability. In front of and behind the adjacent margins of the lower tibiofibular joint are strong transverse bands, the anterior and posterior lower tibiofibular ligaments. In addition, and of vital importance, is the interosseous ligament. These three structures hold the lower ends of the tibia and fibula together and prevent a spreading

\*Presented at the New England Postgraduate Assembly, Cambridge, Massachusetts, November 13, 1940.

†Professor of clinical surgery, Columbia University College of Physicians and Surgeons, attending surgeon, Fracture Service, Presbyterian Hospital, New York City.

of the mortise. The anterior and posterior tibio-talar ligaments are rather weak and of minor significance. The medial collateral ligament is a broad band passing from the under aspect of the medial malleolus forward, downward and backward in a fan-shaped manner, to be attached to the medial aspect of the talus, sustentaculum tali and adjacent surfaces of the navicular. It is a continuous sheet. On the outer side, the lateral collateral ligament is made up of three separate, distinct bands. The medial passes from the tip of the fibula to the outer surface of the os calcis, the anterior goes forward and inward to the body of the talus, and the posterior, which is the strongest, passes almost horizontally inward to the outer tubercle of the talus.

#### *Mechanism of Injury*

When undue strain is brought to bear on the ankle, various things happen. The medial malleolus may give way near its tip or at the base, or the medial collateral ligament may tear. On the outer side, one may find a similar tear of the ligament or lower transverse or higher oblique breaks of the lateral malleolus, or the fibula may give way in its lower shaft. If the strain on the mortise is too great, the lower tibiofibular ligaments may give way or, rarely, tear off a portion of the adjacent tibia. When the force is against the lower surface of the tibia, the posterior or anterior lip may give way.

Considering the problem from the standpoint of the causative factor, one finds that if the foot is overinverted the lateral malleolus may be pulled off, or the medial one pushed off, or the lateral collateral ligament torn. If the foot is everted, the medial malleolus or medial collateral ligament may give way, or the lateral malleolus may be forced off. If the latter holds, the lower tibiofibular ligaments give way. Rotation of the foot on the leg is apt to tear off the medial malleolus, or to give a high spiral fracture of the fibula. With compression, a tibial lip or an extensive comminution of the whole lower tibia may result. When the foot is forcibly driven backward, the wider anterior part of the talus spreads the mortise, and the malleoli or the interosseous ligament gives way.

In a few cases, one of these five forces—inversion, eversion, compression, rotation and backward thrust—may act alone, but usually several act together, especially in the severer injuries. If one enumerates the various combinations of lesions encountered in this region, the list becomes quite alarming. The classification that is useful from a practical standpoint of teaching, treatment and prognosis includes four main groups, with three other less common but serious varieties.

#### *Types of Injury and Their Treatment*

The first group comprises cases of fracture of either malleolus, without displacement and without gross ligamentous injury. These require no reduction, but a brief period (several days) of immobilization and elevation. A posterior molded plaster splint, removed for application of heat, massage and active motion, gives comfort. Weight bearing, with support, is allowed after seven to ten days. Full use is permitted in three to five weeks.

The second group differs from the first only in that there is displacement of the foot, which requires reduction and slightly longer immobilization. In addition to the posterior splint, a sugar tong or bilateral molded splint, to control the inversion and eversion, is used. Weight bearing is allowed about the fourth week.

In both groups, some cases show distinct evidence of marked joint swelling, with a good deal of pain made worse by any movement of the ankle. Relief of this pain can be obtained by aspiration of the joint. Removal of even 4 or 5 cc. of bloody fluid gives marked relief; as much as 15 cc. has been obtained. This should be carried out only with strict precautions, a small nick in the skin being made with a pointed knife and the needle inserted through this rather than forced through the skin.

The third group includes fractures of either malleolus, with tear of the opposite collateral ligament, or bimalleolar fractures with lateral or medial displacement of the foot, but without injury to the tibiofibular ligaments. Reduction is necessary. The foot must be brought into position under the leg, and one must hold the malleoli in place by molding the plaster splint carefully against and beneath the malleoli until the plaster has hardened. It is better to have the splints pass above the flexed knee, to control rotation. They may be shortened after two weeks. Weight bearing, with protection, is started after four weeks.

In the fourth group,—the true Pott's fractures,—in addition to a fracture of the medial malleolus or a tear of the medial collateral ligament, there is a high fracture of the fibula and, most important of all, a disruption at the lower tibiofibular joint. This results in an outward and posterior displacement of the foot on the leg. A satisfactory result depends on a satisfactory apposition of the normal relation, which should be maintained until the various injured structures have healed sufficiently to withstand the strain put on them.

After a careful study of x-ray evidence to determine just what the lesion is, the knee is flexed under anesthesia, to relax the gastrocnemius and to afford countertraction against the thigh. Steady:

downward traction on the foot, the heel being held with one hand and the dorsum of the foot with the other, is gently and gradually applied with increasing force for several minutes. This usually overcomes the lateral displacement of the foot. The hand over the dorsum is then released and used to press backward on the tibia just above the ankle, forcing the foot forward on the leg. The thumb and fingers of the upper hand are used to approximate the malleoli, reducing the disruption of the lower tibiofibular joint. Splints are then applied by an assistant while the position is maintained by the operator, who shifts his hands in such a way as to maintain the traction and forward pressure of the foot, as well as the compression of the malleoli. This must be maintained until the plaster is sufficiently hard. With this type, it is necessary to maintain the immobilization for four to six weeks, although the knee can be mobilized at the end of two weeks. No weight bearing should be allowed for eight weeks, even with support. Disability lasts for three to four months or even longer.

Another type differs from the true Pott's fracture in that the fibula is not broken, but the main lesion is the disruption of the lower tibiofibular joint, with or without a fracture of the medial malleolus. This group is very important, because unless the diagnosis of disruption of the mortise is made and the treatment adjusted accordingly, the patient is very apt to have a permanent, marked disability. Unless firm union is obtained at this joint, the widened mortise leads to instability and persistent pain, which may last for years. If there is any doubt in the surgeon's mind, he should test the ankle under the fluoroscope to see if outward pressing of the foot tends to widen the mortise.

Another group includes cases of extensive comminution of the lower tibia, with any of the other lesions in addition. Accurate reduction can rarely be obtained by manipulation alone. Wire traction through the os calcis, with or without a second wire through the tibia above, sometimes accomplishes a fair reduction, but this type usually belongs in the operative class.

Another type is not a separate group, but includes fractures of either the posterior or the anterior lip of the tibia. The former is by far the commoner injury, and may be found as a complicating factor in any of the groups mentioned above.

Frequent failure to obtain or maintain satisfactory position in complicated ankle fractures, prolonged disability and the frequency of permanent disability have in recent years led me to put more of the severe types of ankle injuries into the oper-

ative class. By means of accurate, internal fixation, it has been possible to dispense with prolonged immobilization by splints and to start active motion a few days after the accident. I now believe that practically every disrupted lower tibiofibular joint should be operated on, and the two bones held in firm approximation by means of a transfixing bolt. In cases complicated by an anterior or posterior lip of the tibia or in comminuted cases, fragments can be realigned and held in position by screws, and small plates have frequently been used on the fibula. The results of this method have been most encouraging, and the disability time has been very markedly decreased.

As in any form of internal fixation of fractures, special technic, instruments and team training are essential, but if treatment is carried out with care, I believe that a great deal of time can be saved and permanent disability avoided.

The walking plaster boot is being used more and more. Certain precautions are indicated. This boot should be employed only when an accurate reduction has been obtained and maintained. It should be applied only after the primary swelling has subsided. Since the dependent position tends to increase congestion and swelling, the patient should be instructed to put his leg up at frequent intervals during the day. Sufficient cotton or sponge rubber should be placed between the sole of the foot and the plaster to lessen pressure. The boot must fit snugly beneath the expanding portion of the upper tibia. One disadvantage of this method is that it prevents the use of any heat, massage or active motions of the ankle. It is very useful, however, for patients who must be up and around for economic or other reasons.

\* \* \*

Fractures around the ankle joint frequently result in a good deal of permanent disability and pain. If the cases are seen early and an exact evaluation of the various lesions is made by careful examination and thorough study of clear x-ray films, excellent reductions can usually be obtained in the first few hours. The method of splinting, the time of immobilization and the question of weight bearing should be determined by the probable length of time required for solid healing of the most serious lesion.

Widening of the mortise due either to disruption of the lower tibiofibular joint or to imperfect reduction is a most disabling affair. Disruption of the mortise can easily be overlooked, and should be searched for in each case. The operative treatment of the more complicated cases, in proper hands, will shorten the period of disability and improve the end results.

## HEREDITARY TELANGIECTASIS

## Report of a Case

LAWRENCE I. STELLAR, M.D.\*

BOSTON

**H**EREDITARY telangiectasis is a pathologic condition that occurs in and is transmitted through both sexes. The characteristic lesions—small red or purplish papules—occur in the mucous membranes, especially those of the upper respiratory and gastrointestinal tracts, in the skin and in some viscera. The papules consist of vessels made up of a single layer of endothelial cells and an abnormally thin epithelium. These vessels have a tendency to rupture, and thus give rise to bleeding. Hemorrhage has been reported most commonly in the form of epistaxis but, of course, may be seen elsewhere. The amount of blood loss tends to increase in later life.

The criteria for the diagnosis of this condition have been established by Goldstein<sup>1</sup> and affirmed by Larrabee and Littman<sup>2</sup> as follows: definite heredity, visible telangiectases, with pathologic distribution, and a tendency to bleed from the lesions.

According to Goldstein,<sup>1</sup> at the end of 1930, case reports of this condition involved about 550 members of 90 to 95 families. In spite of its rarity, hereditary telangiectasis should be thought of in the presence of bleeding; otherwise, the correct diagnosis may be missed or delayed. In the following case, the diagnosis was missed at each admission to the hospital.

## CASE REPORT

C. G., a 56-year-old Canadian-born housewife, had been admitted several times to the Boston City Hospital.

From puberty on, she experienced recurrent nosebleeds preceding her menstrual periods. In 1928, she began to have severe nasal bleeding two or three times daily. Occasionally, the bleeding stopped for as long as 2 weeks and then recurred. The blood usually came from both nostrils, and sometimes amounted to a "large wash-basin full."

From time to time, there were "pins-and-needles" sensations in the fingertips. The tongue became sore, and there was some nausea, and generalized weakness. Because of increasing dyspnea, orthopnea and occasional precordial pain on exertion, the patient was unable to walk more than a few feet.

In 1933, she entered the hospital for the first time because of these symptoms. She remained for 2 months, during which she was given a transfusion and iron and ammonium citrate. Three small hemorrhages occurred

from the nose during this admission. Because of home problems, the patient was discharged, with no complaints except fatigue.

After discharge, she continued taking iron quite regularly for about a year and thereafter intermittently. She soon began to suffer again from nosebleeds, mostly from the left side, occurring one to three times weekly. She remained fairly well, however, until 1936, when she developed symptoms similar to those complained of on the first admission—in addition to bouts of vomiting, feverishness, night sweats and some ankle edema.

Eight months later, the patient entered the hospital again. The treatment consisted of transfusions, iron and daily intramuscular injections of liver extract. The patient was discharged in 5 weeks feeling quite well.

From this time on, although the patient at each hospital entry showed marked anemia, the source of blood loss was obscure. In 3 years, during which she took iron intermittently, she had three admissions to the hospital. Her complaints were similar to those noted on the first two admissions, but except for occasional streaks of blood after blowing her nose, no history of gross epistaxis could be obtained. The only other source of blood loss was infrequent bleeding from hemorrhoids. The patient denied tarry stools. Treatment each time was essentially similar to that noted on the last admission and was always effective.

In 1917, after a "blood test," the patient was given intravenous and intramuscular medication for several years. Then, she was told that her "blood was negative." In 1918, she had "rheumatic arthritis" for a few months. She apparently required no bed rest. In 1937, she was told that she had "rheumatic heart disease." Because of her economic situation, her diet had always been rather low in meat.

The hospital records showed that her mother had severe nosebleeds, anemia and telangiectases of the lips, tongue and fingers; an autopsy report at another hospital noted "severe anemia and multiple bleeding points in the gastric mucosa." The patient stated that her grandmother, great-aunt and great-grandmother supposedly died of "bleeding diseases." She had one daughter, who had had no history of bleeding or telangiectasia.

Physical examination showed a well-developed, middle-aged woman, who was orthopneic, dyspneic and pale. On the anterior portion of the tongue, especially, there were several small, round, bright-red papules, 2 to 3 mm. in diameter (Fig. 1). In addition, telangiectases were noted on the left cheek, the mucocutaneous junction of the upper lip, the right conjunctiva, and all over the nasopharynx.

During the patient's first admission, nose and throat consultants found scales in both nares, but no bleeding. At the last entry, a few small telangiectatic spots were seen on the anterior septum and also on the lateral nasal walls. At the mucocutaneous junction of the left naris were two small telangiectatic areas. The left anterior septum showed a large superficial ulcer of the mucosa. The only actual point with crusted blood was over this ulcer. At

\*Formerly, house officer, Third Medical Service (Tufts), Boston City Hospital; resident, First Medical Service (Tufts), Boston City Hospital.

most entries there was clotted, red blood in the left nostril. The palate, the posterior pharynx and the roof of the nasopharynx also showed telangiectases. No attempt was made to treat these lesions, because none could be proved as the source of the bleeding.

The fundi were normal except at the first admission when each fundus showed a small red area suggestive of hemorrhage.

During several admissions, the cardiac findings varied. At one time, a high pitched, blowing systolic murmur was heard all over the precordium, the pulmonic second sound

FIGURE 1 Photograph of Tongue of Patient C G Showing Telangiectases

was greater than the aortic, the heart was slightly enlarged to the left by percussion. On another occasion systolic and presystolic murmurs were heard at the apex. During the last admission, a Grade 2 systolic murmur was heard best in the 4th left interspace, 4 cm to the left of the midsternal line, and a few medium moist rales were present at the right base.

At the last entry, there was a slight tenderness in the right upper quadrant and the liver was felt three or four fingerbreadths below the costal margin. Previous to this admission, tenderness in the right upper quadrant was noted once the liver was questionably palpable another time, and definitely felt down to the umbilicus on another occasion. The spleen was not felt. At the last two admissions there was slight pitting edema of the feet. Rectal examination showed three or four anal tags and small hemorrhoids. The vaginal examination was negative.

On the several admissions the temperature varied from 98.8 to 100.2°F, the pulse from 88 to 124, and the respirations from 25 to 28.

The hemoglobin level and red cell count at the time of each entry and discharge are presented in Table I.

The white cell counts varied from 7400 to 19000. On the occasion when they were elevated they quickly fell to normal. On the first admission the mean corpuscular volume was 98 cubic microns, the mean corpuscular hemoglobin, 137 micromicrograms, and the mean corpuscular hemoglobin concentration 19.5 per cent. From 33 to 145 per cent reticulocytes were found, the latter occurring as a peak count following the administration of

iron. A typical smear showed 82 per cent polymorphonuclears, 15 per cent basophils, 1 per cent eosinophils, 6 per cent small lymphocytes, 2 per cent large lymphocytes, 7 per cent monocytes and 0.5 per cent myelocytes, there were occasional normoblasts, increased and large platelets, poikilocytosis and anisocytosis. One smear showed decreased platelets. The bleeding time was about 4 minutes, once, it was reported to be over 10 minutes. The clotting time was 5 to 8 minutes, on one occasion, it was noted that clot retraction was poor. The tourniquet test was negative, and the prothrombin time was normal. The red blood cells hemolyzed in solutions containing 0.44 to 0.36 per cent sodium chloride.

The cholesterol was 84 mg, the uric acid 47 mg, the nonprotein nitrogen 22 mg, the calcium 88 mg, and the

TABLE I Hemoglobin Levels and Red Cell Counts at Each Admission

ADMISSION	DATE	HEMOGLOBIN LEVEL %	RED CELL COUNT $\times 10^6$
First	1/25/33	8	0.9
	3/7/33	30	7.3
Second	9/14/33	9	1.8
	10/21/37	75	4.4
Third	6/23/38	10	0.9
	7/23/38	64	3.1
Fourth	1/9/39	18 gm	1.2
	1/26/39	64 gm	2.0
Fifth	9/23/40	10	1.2
	11/5/40	56	2.8

phosphorus 37 mg per 100 cc. The phosphatase was 4.3 Bodansky units, and the icteric index 2. The blood was Type IV (Moss); the blood Hinton reaction was negative, and the formal gel test was negative.

The urine showed a specific gravity of 1.008 to 1.011, a negative test for albumin and a few white blood cells per high power field in the sediment. The specific gravity on each sample of urine obtained was in this range. No concentration tests were done.

No stools were studied at the first admission; on the second admission one stool gave a +++ guaiac reaction, on the third admission, many stools gave up to ++++ guaiac reactions and were still strongly positive on discharge; at the fourth admission one stool was benzidine negative and on the fifth admission many stools gave + to ++++ guaiac reactions and were strongly positive on discharge.

Typical electrocardiogram showed a sinus bradycardia and rather low voltage.

Gastric analyses on four occasions showed no free hydrochloric acid even after histamine. On the first analysis no guaiac test was recorded. The other three were done during the last admission and the tube was passed through the mouth on each occasion. One was guaiac negative and the other two showed gross fresh blood.

Two barium enemas showed incomplete filling of the cecum; a third examination 6 months later was completely negative.

Three gastrointestinal series were negative. The last was done with follow-through studies because of the barium enema results first obtained.

Sigmoidoscopy showed a normal pale mucosa.

Following final discharge the patient was observed for 6 months. The hemoglobin level and red cell count climbed slowly to 65 per cent and 3,500,000, respectively, although the stools showed a persistent ++ to +++ guaiac reaction.

## DISCUSSION

In most cases of hereditary telangiectasis, the hemoglobin very rarely falls to such low levels as those recorded in this case. Houser<sup>3</sup> states that the mortality from hemorrhage is 4 per cent. In most of the cases in the literature, the hemoglobin was noted to be from 50 to 60 per cent.

The patient's diet, which had not been completely adequate, could not explain the picture of anemia without obvious bleeding. During the first two admissions, the source of the blood loss was obvious. In subsequent admissions, the nose could not be incriminated, except for the possibility of postnasal drip, of which the patient was unaware. This was never observed during the last admission, even though she was examined before arising from the horizontal position in the morning.

The only obvious bleeding point in the later hospital entries was a superficial ulcer on the septum. This showed clotted blood on several admissions. The aural consultants did not consider this lesion sufficient to cause the marked anemia. O'Kane<sup>4</sup> reported a case with a ++++ guaiac reaction in the stool that cleared only on treatment of the nasal telangiectases with a sclerosing solution. In his case, the hemoglobin was 50 per cent, and the red-cell count was 3,100,000.

This patient presented the problem of a possible primary lesion in the gastrointestinal tract, as suggested by the first barium enemas. She had a large liver on several entries; this was noted definitely for the first time, three years before the last entry. During the last admission, the liver did not shrink more than 1 cm. as the cardiac failure was relieved. No nodularity of the liver was observed. A final gastrointestinal series and another barium enema six months later did not reveal a cecal lesion. The patient's good and repeated response to treatment and the failure to lose weight also militate against the view that a primary cecal lesion might have been responsible for the melena.

Boston<sup>5</sup> and Goldstein<sup>1</sup> presented cases of gastric hemorrhages due to telangiectases. In the case reported above, two gastric analyses during the last admission showed fresh blood, although the samples were removed through the mouth; however, a properly handled Levin tube does not usually give fresh blood. The mother's autopsy showed "bleeding points" in the gastric mucosa. Gastrointestinal telangiectases must be strongly considered in both the patient and her mother.

Fitz-Hugh<sup>6</sup> has drawn attention to a marked intolerance to blood transfusion, resulting in severe jaundice, in patients with Type IV blood and splenomegaly and hepatomegaly. This patient was Type IV and presented hepatomegaly, but no splenomegaly. She had eight transfusions. Three moderate chills, one with vomiting, were the only reactions recorded.

One final interesting fact has been noted by several observers—namely, the disappearance of some lesions and the appearance of others. Apparent fundic lesions described in the first admissions have since disappeared.

## SUMMARY

A case of hereditary telangiectasis that fulfilled the criteria for diagnosis is presented. The patient showed a very marked anemia on repeated occasions, at first because of nasal hemorrhage, later possibly as a result of gastrointestinal bleeding. The possibility of a separate pathologic lesion in these cases must be kept in mind, but this seems to be ruled out in the case under discussion.

## MEDICAL PROGRESS

HEMATOLOGY: ANEMIA, WITH PARTICULAR REFERENCE TO  
THE HEMOLYTIC SYNDROME\*

WILLIAM DAMESHEK, M.D.†

BOSTON

**A**NEMIA is but a symptom and is therefore always secondary to some other disorder, and so-called "primary" anemia is a thing of the past. Modern classifications of anemia stress cell size and the color index. Thus, anemias are either macrocytic, normocytic and microcytic or hyperchromic, normochromic and hypochromic. These classifications are very useful, since macrocytic, hyperchromic anemias are often deficient in "liver-extract" or vitamin B complex; normocytic, normochromic anemias often indicate that the bone marrow itself is involved by hypoplasia, aplasia, sclerosis, leukemia or metastatic cancer, whereas microcytic hypochromic anemias usually mean that red-cell formation is normal but that hemoglobin is either lacking (iron-deficiency anemia) or cannot be properly synthesized.

## HYPOCHROMIC MICROCYTIC ANEMIAS

A deficiency in iron for the available red-cell formation in both the bone marrow and the blood results either from continued blood loss or from such abnormalities as an inadequate intake of iron in the food, achlorhydria, malabsorption from the bowel and multiple pregnancies. Usually, multiple etiologic factors are necessary before a well-defined anemia results. The condition often known as idiopathic or primary hypochromic anemia, which is usually described in middle-aged women, is also the end result of numerous factors, the most important of which is perhaps the complete histamine achlorhydria. That this condition may be a forerunner of pernicious anemia has been stated a number of times. Miller and Dameshek<sup>1</sup> report 2 cases of primary hypochromic anemia that terminated as pernicious anemia. The first case showed "sideropenic dysphagia," generally known as the Plummer-Vinson syndrome, and developed pernicious anemia a number of years after a typical hemoglobin deficiency had been found. The second case appeared to be a typical case of chronic iron deficiency until iron was

given, following which the features of pernicious anemia became apparent. These cases are of some theoretical interest, since they indicate that the gastric mucosa may first be incompletely atrophic, leading to a disturbance in the digestion of iron-containing foods, and later completely atrophic, resulting in such great diminution in the secretion of Castle's enzyme that the liver-extract deficiency state known as pernicious anemia results. It is probable, as Miller and Dameshek pointed out, that the gastric disturbance starts early in life and, if sufficiently marked in adolescence and early adulthood, may result in the development of the iron-deficiency anemia known as "chlorosis." This condition is by no means extinct, as both Alsted<sup>2</sup> and Olef<sup>3</sup> have shown. Although Olef attempts a clear-cut discrimination between chlorosis and the so-called "primary hypochromic anemia," such a differentiation is probably to be questioned, since the cases merge into one another and, except for age, are really identical in underlying physiology, objective signs and response to therapy. Chlorosis is in all probability idiopathic hypochromic anemia in a somewhat younger age group than most of the cases. When the latter are analyzed, however, a history of long-standing anemia extending back fifteen to thirty years is usually obtained. This illustrates again the value of analyzing the life history of a disease rather than of interpreting it from a single snapshot.

Work on the absorption and metabolism of iron by means of radioactive iron continues in several laboratories.<sup>4</sup> Ross and Chapin<sup>5</sup> found that the greatest absorption took place in patients with chronic hypochromic (presumably, iron-deficiency) anemia. By this method, cases of pernicious anemia were found to have an iron deficiency that became apparent only after the erythrocyte response to liver extract had occurred. Fowler and Barer,<sup>6</sup> who studied this problem without recourse to the radioactive technic, suggested that iron had, in addition to its action as replacement therapy, a stimulating effect on hemoglobin formation. In another investigation, the same authors<sup>7</sup> discovered that the addition of copper sulfate to the iron preparation (ferric ammonium citrate) used did not

Reprints of articles in this series are not available for distribution, but the articles will be published in book form. The current volume is *Medical Progress Annual, 1940* (Springfield, Illinois: Charles C. Thomas Company, 1941. \$1.00).

increase the effectiveness of iron in the hemoglobin regeneration of mild hypochromic anemia in the adult.

### HYPERCHROMIC MACROCYTIC ANEMIAS

#### *Pernicious Anemia*

Despite minor modifications, Castle's theory regarding the interaction of intrinsic factor derived from the stomach and extrinsic factor derived from the food continues to stand firm. Very careful and elaborate observations by Formijne<sup>8</sup> demonstrated again that liver extract was not formed by the interaction of extrinsic and intrinsic factor in vitro, and could be produced only in vivo. A series of carefully controlled observations in swine—in which total gastrectomy was performed, the animals killed at various intervals, and the livers assayed for potency by testing in human cases of pernicious anemia—is reported by Geiger, Goodman and Claiborn.<sup>9</sup> Following total gastrectomy, the liver gradually became depleted of antianemic potency; this indicates that it serves either as a storage reservoir or as an elaborating and storing center. By other ingenious experiments, it was confirmed that gastric digestion was essential for the production of the erythrocyte-maturation factor, although it was also shown (as Meulengracht had previously indicated) that the duodenum is a significant source of intrinsic factor. Despite removal of the entire stomach and the duodenum, with great reduction in the antianemic potency of the swine's liver, it was, however, impossible to produce in these animals the typical human blood picture of pernicious anemia. Ivy<sup>10</sup> and Wintrobe and his co-workers<sup>11</sup> have also failed to produce the blood picture of pernicious anemia either by gastrectomy in various animals or by the use of a diet grossly deficient in various factors of the vitamin B complex. Wintrobe et al. were, however, able to produce neurologic phenomena closely resembling those found in pernicious anemia by a diet deficient in pantothenic acid, pyridoxin and choline. Whether these studies have any definite relation to pernicious anemia remains to be seen.

The long-standing question regarding the relation of the fish tapeworm (*Diphyllobothrium latum*) and pernicious anemia is still under discussion. Von Bonsdorff<sup>12</sup> reports 14 typical cases of pernicious anemia in carriers of the worm. In the first 9 cases, treatment with an anthelmintic filicin was followed by a distinct reticulocyte response and a complete remission; liver extract was not used. Reticulocytosis began directly after expulsion of the worm. In 1 case, liver extract was necessary for a complete remission. In the last 4 cases, the worm cure had little or no effect on the anemia, which was completely relieved by

liver extract. In these cases, there was apparently only a coincidental relation between the simultaneous presence of the worm and the severe anemia. Von Bonsdorff believes that in many cases the tapeworm interferes with the absorption of the liver-extract substance from the bowel, and that although the anemia can be cured with liver extract, removal of the worm is of fundamental importance.

Jones<sup>13</sup> and Meyer, Schwartz and Weissman<sup>14</sup> discuss the problem of gastrectomy and the anemias. Jones states, "It is apparent that major gastric surgery may be performed without any great fear of undue consequences as far as the factor of normal hematopoiesis is concerned . . . [although] an occasional severe microcytic or macrocytic anemia may ensue . . . many months following operation." Meyer and his co-workers report such a case, which five years after complete gastrectomy developed pernicious anemia. The value of long-continued observation of patients who have undergone extensive gastric operations is stressed.

Although pernicious anemia in the Negro is usually considered extremely rare, McCracken<sup>15</sup> reports 3 cases and states that the incidence of the disease in the Negro is 1 per 100,000, as compared with 35 per 100,000 in the white race. Schwartz,<sup>16</sup> who has observed a large number of cases of pernicious anemia in Negroes at the Cook County Hospital, Chicago, stresses the diagnostic difficulties in some of the cases, which may masquerade as a subacute or chronic infectious process.

Treatment of the disease has been quite well standardized in this country, since the various products have been assayed and labeled according to their unit potency. Such assays must still be performed in previously untreated human cases, because no satisfactory animal method has been found. Worth watching, however, is the method of Crandall, Finne, and Smith,<sup>17</sup> which utilizes dogs with internal bile fistulas (anastomosis of the gall bladder to the right renal pelvis, with ligation of the common bile duct). A hyperchromic, macrocytic anemia, apparently responding to liver extract, gradually follows this operation. Jacobson and Subbarow<sup>18</sup> report on recent advances in the purification of active substances from liver extract. Although the primary factor has still not been obtained in crystalline form and several factors are probably required to give the full effect, these investigators report that recent refinements in preparation have resulted in the development of a material that is highly effective in an average dosage of only 7 mg. every ten days.

Askey,<sup>19</sup> arguing that the liver in a case of pernicious anemia is completely lacking in specific

substance, suggests the use of a single massive dose of liver extract (150 to 400 U.S.P. units) given intramuscularly without other treatment. Clinical and hematologic responses were excellent and well maintained in the majority of the cases for several months. A massive initial dose to "stock the liver," followed by monthly doses to maintain adequate storage, appeared sufficient to give optimum results in most cases. This method of therapy cannot be recommended. It is not known how much of the massive dose is quickly excreted in the urine; stocking the liver is not the essential thing; curing the liver-extract deficiency throughout the body is essential, and the most physiologic method possible should be used. For this reason, regular doses—preferably every week or two—are far preferable, although still not entirely physiologic. Evans and Jordan<sup>20</sup> found that a highly concentrated liver-extract preparation in 1-cc. doses parenterally was more effective both hematologically and neurologically than the cruder preparations. Neural symptoms and signs were controlled or actually improved in the great majority of cases. Zillhardt, MacLean and Murphy<sup>21</sup> found that the combination of thiamin (vitamin B<sub>1</sub>) and parenteral liver extract "might have a beneficial effect on those residual neural signs and symptoms of pernicious anemia that seemed stationary in spite of persistent, intensive anti-pernicious anemia therapy." The authors rightly advise caution in the interpretation of their results. No effects were obtained when the vitamin was given orally, or when vitamin B complex (containing thiamin) was given parenterally.

#### HEMOLYTIC SYNDROMES

Interest in the numerous hemolytic syndromes continues to run unusually high. They may be classified as follows:

- A. Hemoglobinurias (exceedingly rapid hemolysis, with hemoglobinemia and hemoglobinuria)
  1. Paroxysmal cold
  2. Paroxysmal nocturnal
  3. March
  4. Favism
  5. Unclassified types
- B. Hemolytic anemias
  1. Hereditary
    - a. Spherocytic
    - b. Target-cell (Mediterranean)
    - c. Sick-cell (African)
  2. Acquired (acute, subacute and chronic types)
    - a. Chemical, including the sulfonamide drugs
    - b. Immune body (hemolysins and agglutinins), including erythroblastosis foetalis
    - c. Idiopathic, including hypersplenic types
    - d. Symptomatic

Although this classification seems to offer some help, it is realized that it probably has only transitory significance. It is somewhat unorthodox in that hereditary (usually called "congenital") hemolytic jaundice or anemia, which is generally considered to be spherocytic, is subdivided into spherocytic, target-cell and sickle-cell types; it will be noted, furthermore, that erythroblastosis foetalis is included under the acquired hemolytic processes in association with the presence of immune bodies.

#### Mechanisms

Much discussion continues to center about the etiologic mechanisms relating to the hemolytic syndromes. In some, as in paroxysmal cold hemoglobinuria, these have been rather well worked out; in others, they are as obscure as ever. It should be realized that increased blood destruction may be due to numerous causes and that multiple mechanisms are often present. A theory that attempts to explain all the hemolytic syndromes on the basis of a single mechanism must on occasion be stretched rather fine. Theories at present being discussed are as follows:

*Hereditary defect of "erythron."* This is accepted by most authors as the cause for congenital spherocytic hemolytic jaundice, and perhaps also for the target-cell and sickle-cell types. Unless they are caused by some definite etiologic agent, many acquired cases with spherocytosis are even said by extreme protagonists of this view to be due to a congenital defect of the red cells, latent for many years.

*Stasis.* The chief protagonists of this theory are Ham and Castle,<sup>22</sup> who point out that stasis results in increased spheroidicity of the red cell and, ultimately, in its hemolysis. Hemolytic reactions are thought to be due to extreme stasis, especially in the spleen, or to agglutinative reactions. This theory does not explain, among other conditions, march hemoglobinuria or the hemolytic syndromes associated with actual hemolysins.

*Hemolysins.* Dameshek and Schwartz<sup>23</sup> found hemolysins in the blood in certain cases of acute hemolytic anemia, and by the injection of immune hemolysins they were able to reproduce spherocytosis and various types of hemolytic syndromes.<sup>24</sup> They contended that hemolysins might be at the bottom of many of the hemolytic syndromes, including congenital spherocytosis. If by "hemolysin" is meant an agent—chemical, immune-body or cellular—that causes injury to red cells, this idea may be well taken, although the hemolysis of simple stasis, unusual exertion and so forth is not explained. Although Ham and Castle prefer to designate the hemolysis following agglutination

as a phenomenon of stasis, Dameshek and Miller<sup>25</sup> have shown that agglutination causes injury to the red-cell envelope, with the result that it becomes readily vulnerable to mechanical trauma, stasis and the effects of complement activity.

*Lysolecithin.* Bergenhem and Fahraeus<sup>26</sup> demonstrated that normal blood serum contains a lytic substance, which they called "lysolecithin." They demonstrated that it became increased with stasis and concluded that it was responsible for normal blood destruction in the chief organ of stasis—the spleen. They suggested that hemolytic anemias might simply be due to an increased concentration of lysolecithin acting on the erythrocytes passing slowly through the spleen. Singer<sup>27</sup> described a method for the extraction of lysolecithin from the serum and for quantitative measurement of its hemolytic power. He also described the lysolecithin fragility test, apparently specific for the spherocytes of congenital hemolytic jaundice. In a later paper, Singer<sup>28</sup> pointed out that "the significance of lysolecithin as the physiological hemolysin involved in the mechanism of normal blood destruction . . . is not conclusive," and that it was not likely that lysolecithin could be regarded as responsible for the increased blood destruction in congenital hemolytic jaundice, especially since no increase in the production of this lysin was demonstrable in the disease. Singer concluded that lysolecithin, although it had hemolytic qualities, was not the hemolysin causing hemolytic anemia.

*Spleen.* Because of the dramatic effects of splenectomy in many cases of hemolytic anemia, of both the congenital and acquired types, the spleen has naturally been singled out as the chief offender by most observers. What the spleen actually does still remains a mystery. According to Ham and Castle,<sup>22</sup> it acts like a test tube, allowing normal red cells to stagnate and become somewhat spheroidal and causing the abnormal spherocyte to become hemolyzed. According to Bergenhem and Fahraeus,<sup>26</sup> lysolecithin and the spleen are closely related. Dameshek and his co-workers<sup>24, 29</sup> assume that the spleen is the chief organ of hemolysin production, and other observers, notably Doan,<sup>30</sup> arrive at a somewhat similar conclusion by stating that blood destruction has to do with the reticuloendothelial system, of which the spleen is the largest factor. That some cases of hemolytic anemias are solely hypersplenic cannot be denied; in others, the spleen seems to be secondarily enlarged, and splenectomy may or may not be of value. Direct observation of the living spleen in the rat by means of transilluminated quartz rod was first performed by Knisely,<sup>31</sup> and on the basis of his work, it seemed clear that

circulation in the spleen is of the closed variety and that blood often stagnates there, perhaps for hours. However, in a more recent communication, MacKenzie, Whipple and Wintersteiner,<sup>32</sup> using a modification of the same technic, came to diametrically different conclusions—that is, that the spleen possessed an open circulation and that the pulp spaces, not the venous sinuses, were the primary physiologic units of the splenic vascular mechanism. Studies of the spleen in experimentally produced hemolytic anemia revealed that spherocytes were trapped outside sinusoids and then presumably became hemolyzed. Singer, Miller and Dameshek<sup>29</sup> studied subjects splenectomized for various causes and found that blood destruction, as measured by the fecal urobilinogen output, became greatly reduced; this might be associated with the fact that a thinner, more resistant cell population, together with increased numbers of target cells, was present. The spleen was found to have other functions, which are described below. From all these studies, it may safely be concluded that the exact relation of the spleen to hemolytic anemia is not yet clear, nor can one say with any degree of assurance which of the various theories described above fits most closely the pattern of the observed facts.

### *Hemoglobinurias*

*Paroxysmal nocturnal hemoglobinuria.* This disorder, which has been studied extensively by Ham<sup>33</sup> and by Ham and Dingle,<sup>34</sup> is associated with an increase in the acid fragility of the red cells. The fundamental cause of the disorder remains obscure, although there is some evidence that the red cells are injured by an immune body (hemolysin?) since complement results in hemolysis. Ham and Horack<sup>35</sup> made the interesting observation that certain cases of chronic hemolytic anemia may not show the characteristic nocturnal episodes of hemoglobinuria except at infrequent intervals. The acid fragility test of Ham thus becomes an important diagnostic test in atypical hemolytic syndromes, especially when splenectomy is being considered, since removal of the spleen is without therapeutic effect in paroxysmal nocturnal hemoglobinuria.

*March hemoglobinuria.* Gilligan and her collaborators<sup>36, 37</sup> have made careful studies of the interesting condition known as march hemoglobinuria. In this curious condition, first described in soldiers, "black water" develops with specific types of exercise, such as strenuous marching and running. Hemoglobinuria does not develop when the patient assumes a kyphotic instead of a lordotic position while exercising. Gilligan et al. studied the

renal threshold for hemoglobin in the blood plasma, its quantitative excretion in the urine, the spectrophotometric analysis of the pigment and various possible pathogenetic mechanisms. No clues regarding the etiology of the condition were found, although much useful information concerning the pathologic physiology of the hemoglobinurias was obtained.

**Favism.** Luisada<sup>38</sup> has contributed a comprehensive article on favism, which he considers "a singular disease chiefly affecting the red blood cells." This condition, which is chiefly restricted to the inhabitants of Sardinia, results either from the ingestion of the fava bean or from inhalation of its flowers, and is characterized by the sudden appearance of hemoglobinuria, jaundice and vascular symptoms. Luisada believes that the condition represents an anaphylactic reaction in which the red cells are directly injured.

**Other hemoglobinurias.** Altschule and Gilligan<sup>39</sup> report a case of acute, massive hemoglobinuria in an old man without demonstrable cause and bearing, apparently, little relation to the other types of hemoglobinuria. This study is distinguished chiefly by the careful measurements of the various metabolic changes in blood pigment, and by the discussion of the differential diagnosis of hemoglobinuria. Calculations of the amount of hemoglobin lost during the attack, as computed by various methods, showed that approximately 1400 cc. of blood was hemolyzed during the first week, 400 cc. during the second week, and 200 cc. during the third. In another paper, Gilligan and Kapnick<sup>40</sup> reported hemoglobinuria occurring during treatment with sulfanilamide. It is recommended that, in addition to transfusions, sodium bicarbonate be added in sufficient quantity to keep the urine alkaline. This is said to protect the kidneys against damage caused by deposition of hemoglobin pigment in the tubules.

### *Hereditary Hemolytic Anemias*

**Spherocytosis.** Lloyd<sup>41</sup> has contributed a significant (unfortunately not very accessible) monograph on the etiology of "acholuric family jaundice," in which the various abnormalities in the disease are assessed according to the theories discussed above. Singer's<sup>28</sup> finding that the spherocytes of this disease are abnormally fragile to lysolecithin is confirmed, and Lloyd also agrees with Singer that there is not enough evidence to incriminate lysolecithin. Some very ingenious experiments are recorded in which exsanguination was performed on a newborn monster and transfusions were given (on separate occasions) from 2 persons with congenital hemolytic spherocytic

jaundice, one of whom had been splenectomized, the other being an active case. The recipient lived long enough for observations to be made. Whereas the red cells of the splenectomized patient became rapidly more spherocytic and were quickly destroyed in the circulation of the monster (who possessed a normal spleen), the red cells of the active spherocytic case became no more spherocytic than in their own circulation. From these observations, the author concludes:

The pathological blood destruction of the disease is dependent upon the inheritance of an abnormality of the erythron. As the result of this defect the red cells are abnormally susceptible to damage in their passage through the spleen by a process which, very probably, causes little or no permanent damage to the normal erythrocyte. . . . It is possible that lysolecithin . . . will cause permanent damage to the red cells of acholuric family jaundice, indicated by spherocytosis which persists until the death of the cell, but which is not sufficient to cause permanent alteration in the normal erythrocyte.

These in vivo experiments result in conclusions similar to the in vitro findings of Ham and Castle,<sup>22</sup> but they still do not explain the "why" of the congenital spherocytosis, which may be the result of the activity of an inherited hemolytic factor on the non-nucleated erythrocyte. Nor is the abnormally diminished blood destruction following splenectomy in this congenital type of hemolytic jaundice explained<sup>42</sup>—that is, although spherocytosis is still present, blood destruction is less than normal, indicating that the spherocyte has a normal resistance within the circulation and that the spleen has an active (hemolytic?) effect in destroying erythrocytes. This is also indirectly brought out in the report of a series of 3 cases of hemolytic crisis occurring in 3 members of one family with hereditary spherocytic jaundice.<sup>42</sup> That all these persons developed very severe anemia, necessitating emergency splenectomy within a few days of each other, makes it possible that the cause of the suddenly enhanced spherocytosis was outside the marrow and perhaps splenic in origin.

Dameshek and Singer<sup>43</sup> direct attention to a type of familial jaundice without bile in the urine and nonhemolytic in type (familial nonhemolytic jaundice). This condition, in which persistent although somewhat variable and usually mild jaundice is present, may be confused either with familial hemolytic jaundice or with mild hepatic disease. It is distinguished from the former by the normal size, thickness and fragility of the red cells, by the lack of reticulocytosis and by the absence of all evidence of increased blood breakdown, particularly in the fecal urobilinogen out-

put. It is distinguished from hepatic disease by the long course, its familial nature and the complete normality of the liver-function tests. As demonstrated by the bilirubin-excretion test, the condition is apparently due to a delayed excretion of indirect bilirubin from the blood stream by the liver cells, with resultant retention. The liver itself is histologically normal, as recently shown by Krarup and Roholm.<sup>44</sup> A very careful evaluation of the bilirubin-excretion test is that of Weech, Vann and Grillo.<sup>45</sup>

*Target-cell anemia.* Under this designation, I<sup>46</sup> described the case of an Italian youth who showed marked hypochromic anemia, jaundice, marked splenomegaly, generalized osteoporotic changes and the presence of many target cells in the blood. These cells, which look like a target or bull's eye in stained preparations, are abnormally thin and unusually resistant to hypotonic saline solutions. Because this patient presented most of the features of Cooley's anemia, and because cases of this Mediterranean disease show not only nucleated red cells but target cells and increased hypotonic resistance in the blood, the possibility was broached that the fundamental defect in both conditions was the target cell. Wintrobe, Matthews, Pollack and Dobyns,<sup>47</sup> reporting a similar condition in 14 members of three Italian families, stated that both Cooley's anemia and this milder Mediterranean condition represented an inherited defect—the production of unusually thin red cells. Other reports of what is probably the same condition are those of Strauss, Daland and Fox<sup>48</sup> and of Eliel and Bayles.<sup>49</sup> From further studies of these conditions,<sup>50</sup> it appears that familial target and oval syndromes are relatively common in Italian families, that they are inherited as a dominant characteristic, and that great variabilities occur in their severity. Thus, Cooley's anemia appears to be the severest form, and target-cell anemia the next, a number of milder forms ("hypochromic polycythemia," refractory hypochromic anemia and so forth) being known.

Bohrod<sup>51</sup> rightly points out that the target cell is commonly found in many, particularly hypochromic, anemias. Barrett<sup>52</sup> first noted that these cells were found in unusually large numbers in sickle-cell anemia, following splenectomy and in obstructive jaundice and steatorrhea. Singer, Miller and Dameshek<sup>53</sup> found them constantly in splenectomized patients and explained the increased hypotonic resistance of the red blood cells on this basis. Bohrod attacks the concept that the target cell represents a cell that is perhaps defective, and maintains that it is merely representative of increased blood regeneration secondary to blood de-

struction or blood loss. This view does not agree with the observations that, following splenectomy, blood destruction is conspicuously diminished and target cells become greatly increased, that, in the familial Mediterranean cases, target cells are frequently numerous without any evidence of increased blood destruction, that, following splenectomy in Cooley's anemia, large numbers of target cells appear or that these cells are absent from cases of congenital and acquired spherocytic jaundice in which blood destruction is greatly increased.

*Sickle-cell anemia.* Bauer<sup>53</sup> contributes a comprehensive article on sickle-cell disease, in which valuable considerations regarding pathogenesis and the generalized character of the condition are discussed. Anemia is only one consequence of the sickle-cell trait, and is much less serious than the circulatory stasis in the small blood vessels of the internal organs, which is perhaps the primary and most disastrous consequence of the disease. Such stasis may be enhanced by surgical procedures and may be the fundamental cause of the anemia. It is recommended that all Negro patients be routinely examined for the sickle-cell trait, since this condition may result in disorders mimicking rheumatic fever, rheumatic heart disease, polyarthritis, osteomyelitis, various infectious diseases, cerebral conditions, peptic ulcer, appendicitis and so forth. Sickle-cell anemia with unusual bone changes is reported by Danford, Marr and Elsey,<sup>54</sup> with central-nervous-system involvement by Hughes, Diggs and Gillespie<sup>55</sup> and by Skoog,<sup>56</sup> and with ulcers of the legs by Cummer and LaRocco.<sup>57</sup> The reason for the development of these ulcers is still obscure despite very careful studies. Methods for the determination of the sickle-cell trait are described by Diggs and Pettit<sup>58</sup> and by Sherman.<sup>59</sup> The moist stasis method—Scriver and Waugh<sup>60</sup>—is recommended by Diggs and Pettit. Sherman describes a method for differentiating the sickle-cell trait and sickle-cell anemia by injecting red cells kept free from outside air into a solution of saline formalin. Since the sickle-cell trait may have no clinical significance, it is essential to differentiate it and the actual sickle-cell anemia.

#### *Acquired Hemolytic Anemias*

Fox and Ottenberg<sup>61</sup> present a careful study of the acute hemolytic anemia resulting from the sulfonamide drugs. This may be so severe as to result in shock and even death; in fact, 6 of their 9 cases ended fatally. The fundamental mechanism of the blood destruction is still obscure, although it may be allergic or due to the formation of unusual oxidation products that are

allergic or hemolytic. Emerson, Ham and Castle<sup>62</sup> came to similar conclusions. Fox and Ottenberg found that twelve to forty-eight hours after onset of hemolysis, the serum contained three blood pigments: hemoglobin, methemoglobin and Fairley's new pigment—methemalbumin.

Farrar, Burnett and Steigman<sup>63</sup> report a case of acquired hemolytic anemia in which a serum isohemolysin was found, similar to that found in the cases of Dameshek and Schwartz.<sup>23</sup> Splenectomy was curative.

Recent experience with cases of acute and subacute acquired hemolytic anemia of idiopathic variety reveals that only occasionally are hemolysins demonstrable. Splenectomy, although usually curative, may not result in recovery, particularly if the operation has been postponed too long while numerous transfusions have been given. Under these circumstances, not only may new agglutinins or hemolysins be built up, but unusual myeloid metaplasia may develop in spleen or liver. Cases of this sort may then not respond to splenectomy. In such cases, one should determine whether greatly increased blood destruction is present and should be sure that no underlying cause, such as leukemia or Hodgkin's disease, is present; only a minimum number of transfusions (one to three) should be given before splenectomy is performed. Many cases in infants and young children are probably of a milder form (so-called "Lederer's anemia"), and these patients frequently, but by no means always, recover without splenectomy. Such a case is reported by Sterner.<sup>64</sup>

Levine, Katzin and Burnham<sup>65</sup> indicate that erythroblastosis foetalis—icterus gravis neonatorum—is acute hemolytic anemia of the newborn and is caused by isoimmunization of an Rh-mother by an Rh+ fetus. The resultant anti-Rh agglutinin may then penetrate the placental circulation and cause agglutination, with consequent hemolysis of the infant's red cells. It is extremely important in these cases to give blood from an Rh- donor—not the mother. If testing for the Rh factor cannot be done, extremely careful cross-matching by means of the Landsteiner test-tube technic should be performed, with the modification that incubation of the serum, red-cell suspension and saline mixture be carried out for at least thirty minutes. By proper transfusion technic in these cases, the mortality rate should be considerably reduced.

The possibility that some cases of acquired hemolytic jaundice are secondary to some underlying process such as leukemia, Hodgkin's disease, lymphosarcoma or dermoid cyst is suggested by

Singer and Dameshek.<sup>66</sup> In one remarkable case, in which splenectomy resulted in only a temporary response, the finding and removal of a dermoid cyst resulted in complete cure.

**CASE RECORDS OF THE  
MASSACHUSETTS GENERAL HOSPITAL**ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor***CASE 28091****PRESENTATION OF CASE**

A fifty-two-year-old Canadian architect was admitted to the hospital because of dyspnea of several months' duration, following a series of neuromuscular symptoms extending over a period of years, for which he had been seen in the hospital previously.

About ten years before this last entry, there was gradual onset of numbness and tingling in the hands and feet, *sensation remaining unimpaired*. About six years later, the patient began to have progressive difficulty in walking, and became unsteady on his feet. Four months after this, he was admitted to the hospital, when the pupils were irregular and unequal, and reacted to distance though not to light. There was slight drooping of the upper lids. The legs appeared small, but not definitely atrophied. Deep tendon reflexes could not be obtained in arms, knees or ankles. Vibration sense was absent in the malleoli. Physical examination was otherwise negative. The blood Hinton reaction was negative. The cerebrospinal fluid showed a total protein of 80 mg. per 100 cc., a gold-sol curve of 0012210000, a negative Wassermann reaction and negative microscopy and dynamics. Other laboratory studies were negative. After discharge from the hospital, the patient was given various forms of arsphenamine treatment, which was discontinued because of severe reactions. The symptoms remained stationary for a few months. A right-foot drop then developed, requiring the use of a cuff about the foot, wired to a cuff about the calf, as an aid in walking. The right arm and right leg gradually became increasingly atrophic.

Eleven months before the last admission, the patient experienced unusual dyspnea and prostration, in the course of a coryza lasting several days. A similar attack, lasting three days, occurred seven months later. The dyspnea appeared to be paroxysmal, and was unassociated with any disturbance of heart action. A physician prescribed coramine. The patient went to the White Mountains for a short vacation, and returned after a week, complaining that the slight change in altitude had brought on a return of the dyspnea, with a

dry cough. He had a rise in afternoon temperature to 99 or 100°F. His physician noted a distinct expiratory murmur over the middle of the right lung, posteriorly, without rales or areas of dullness. The blood pressure was 110 systolic, 90 diastolic. A roentgenogram of the chest showed old apical tuberculosis on the right, with apparently enlarged lymph nodes at the hilus. Ten days before entry, there was rapid progression of the attacks of dyspnea, and the patient began to lose strength. His cough continued to be unproductive. He had no chills, sweats or chest pain. The blood pressure was 90 systolic, 70 diastolic, at this time. On the advice of a consultant, he was readmitted to the hospital.

The patient's father died of tuberculosis at forty-six years of age. The patient himself, when fifteen years old, spent a year at rest because of a suspicion of tuberculosis. Subsequently, the patient had never been vigorous, although he was seldom sick in bed. He had lived for two years in the Philippine Islands. Exposure to syphilis was denied. Shortly before the onset of the respiratory symptoms, an employee with whom he had worked in close contact for years was diagnosed as tuberculous.

On admission, the patient appeared well developed and nourished but somewhat dehydrated. The lips, fingers and upper chest were cyanotic. The veins of the neck and upper extremities were distended. The lower extremities were pale and cool. The heart was slightly enlarged. The pulmonary second sound was moderately loud, and there was a fairly loud systolic murmur, heard best over the lower half of the heart and toward the apex. There was dullness, with bronchial breathing, over the upper sternum, and a few fine rales at each base. The liver edge was palpable four or five fingerbreadths below the costal margin. There was slight pitting edema over the sacrum, but not in the extremities. The neurologic status was not reviewed at this time.

The temperature was 99°F., and the pulse was 90 and weak but equal in each wrist. The respirations were 20, without cough or wheeze. The blood pressure was 80 systolic, 40 diastolic.

Examination of the blood showed a red-cell count of 4,780,000 with 13.6 gm. hemoglobin, and a white-cell count of 21,000 with 78 per cent polymorphonuclears, 9 per cent small lymphocytes, 12 per cent monocytes and 1 per cent eosinophils. The blood Hinton reaction was negative. The nonprotein nitrogen was 33 mg. per 100 cc.

Roentgenologic examination of the chest showed marked enlargement of the pulmonary vessels toward the hilus, but not distally, with weak pul-

sations. The lung fields showed mottled and linear areas of increased density. There was questionable dilatation of the right ventricle.

An electrocardiogram showed right-axis deviation. All complexes were inverted in Lead 4, with prominent P waves.

The patient continued dyspneic. He was given oxygen, and a phlebotomy of 300 cc. was performed, without appreciable effect. Death occurred from respiratory failure on the third hospital day.

#### DIFFERENTIAL DIAGNOSIS

DR. J. H. MEANS: This somewhat complicated story divides itself fairly well into two chapters, which I might consider to some degree separately. The history ten years previously and continuing down to four years previously, when the patient was in the hospital for study, was characterized by some paresthesias and later by the development of difficulty in walking, unsteadiness on the feet and irregular, unequal Argyll-Robertson pupils, with ptosis of both eyelids, absent tendon reflexes and absent vibration sense; I cannot reconcile this with anything but tabes, perhaps of a rather burnt-out sort. There is no evidence to point to a diagnosis of combined system disease and no suggestive blood picture, nor is the story typical of such disease. The Argyll-Robertson pupil is fairly pathognomonic. The irregularity may likewise be due to syphilis. The blood Hinton reaction was negative. That does not signify anything because it is often negative in long-standing tabes of an inactive sort. The protein was elevated, and the gold-sol curve was not very impressive, but it had a hump in the middle that would go with tabes satisfactorily, so that I cannot get away from that diagnosis, and I therefore make it without more discussion.

Later, however, there were neurologic findings that were not consistent with tabes. Motor phenomena came on after some arsenical treatment, to which the patient responded poorly. A right-foot drop developed, which required apparatus to permit him to walk, and he developed muscle atrophy in the right leg and also in the right arm. This distribution of atrophy in the right arm and leg sounds as though he had had a cerebral lesion, but since the rest of the picture was very much more like that of a peripheral neuritis I must confess that I am puzzled. However, I believe that the foot drop was almost certainly due to peripheral neuritis. Of course, the reflexes were absent anyway because of tabes. I do not know what would happen to reflexes in the event that a tabetic patient, with no reflexes,

developed hemiplegia from a cerebral accident. What would happen?

DR. CHARLES S. KUBIK: The reflexes would remain absent.

DR. MEANS: Then we cannot say that this patient did not have some cerebral lesion, but I think it is most unlikely, and we have no proof. What I think he had was an arsenical neuritis, which gave him foot drop. Why the right arm rather than the left or some other part was also involved, I cannot say. It may have been just chance. At any rate, I am unable to go any farther with the neurologic diagnosis. I leave it there.

The symptoms in the second period, which began eleven months before entry, instead of pointing to the nervous system, involve the circulatory system in a somewhat puzzling fashion. Certain features about the symptomatology suggest an upper mediastinal pressure syndrome. We are told that the neck veins were dilated and that a venipuncture was performed in the hope of giving relief, and we are also told that the patient was cyanotic in his upper extremities, the upper chest, neck and face, but nowhere else. These manifestations go with an upper mediastinal pressure syndrome, and I dare say that the dyspnea might also be consistent. But other things do not fit that interpretation so well. There is some evidence of edema and congestive failure with a large liver, and perhaps an upper mediastinal pressure syndrome is not the most likely explanation.

Let us consider the various symptoms. As I read the second chapter, I was impressed with the following symptoms. In the first place, the paroxysmal dyspnea was unassociated with disturbance of the heart action. I am interested in the story that, after getting better, the patient became worse when he went to a somewhat higher altitude; this suggests that a relative oxygen want played a part in the dyspnea. The progressive fall in blood pressure may be significant—at any rate, it is very striking. It started as 110 systolic, 90 diastolic, and dropped to 80 systolic, 40 diastolic, shortly before he died. I am also impressed with the fact that there was some evidence of infection: a temperature of 100°F. and a leukocytosis that requires explanation. I am interested that there was evidence of old tuberculosis, with apical and lymph-node involvement. I am rather impressed with the progression of the attacks of dyspnea and the evident marked loss of strength.

The matter of tuberculosis might be discussed for a moment at this point. The patient had been suspected of having it in childhood. He

showed obsolete tuberculosis by x ray study. The exposure to the person with whom he worked in close contact does not impress me as being significant, because it is unlikely that one would catch tuberculosis at his age—he was beyond the age when one contracts new tuberculosis. He had been working with this person for years, however, but we do not know how many. I fancy he had tuberculosis before he established this contact, so that it is not of great importance.

It is to be observed that the patient denied exposure to syphilis, but I believe that he had had it. I do not see how we can escape that conclusion.

When he came into the hospital, the significant signs were the high venous pressure, the loud pulmonic second sound and the loud systolic murmur, heard best over the lower half of the heart and toward the apex. It did not go out to the axilla, like a mitral murmur, and seems to have been more in the region of the pulmonary area. He also had dullness, with bronchial breathing, over the sternum. Dullness there suggests dilatation of the great vessels or a mediastinal mass, or something of that kind that would go with the upper mediastinal pressure syndrome. There may have been some element of upper mediastinal pressure in addition to another factor that produced the rest of the picture. Later, the patient had a palpable liver and pitting edema, and the blood pressure dropped. The laboratory work, except for the leukocytosis and perhaps a monocytosis, does not help us much. The right axis deviation is of interest. The x ray examination described—I have not seen the films—some changes in the pulmonary vessels and some enlargement of the heart in the region of the right ventricle.

May we see the x-ray films and try to pull all this together?

DR. AUDREY O. HAMPTON: At the first examination, one might on first inspection call these enlarged lymph nodes at the lung roots, particularly since the patient had evidence of old tuberculosis, but in this Bucky film one can see that they are blood vessels. The blood vessels of the lung roots are grossly enlarged, and they end rather abruptly in the middle of the lungs.

DR. MEANS: Can you tell whether they are arteries or veins?

DR. HAMPTON: They are probably pulmonary arteries.

The film also shows a few rather short linear scars in the lungs scattered around in queer places below the site of the old tuberculosis; these scars were not present at the examination a month before.

DR. MEANS: Did the patient have emphysema?

DR. HAMPTON: The diaphragm is relatively low, but there was no note of limitation in excursion.

DR. MEANS: What about the upper mediastinum? Is there a mass of any kind?

DR. HAMPTON: No; the trachea is in normal position, and the main bronchi are normal.

DR. MEANS: Is there any stenosis?

DR. HAMPTON: No. This film shows a definite change in the bases of the lungs, as compared with those taken at the examination a month before. It looks like pulmonary edema, in addition to poorly outlined areas of consolidation.

DR. MEANS: Are these areas of fibrosis?

DR. HAMPTON: I think that this upper shadow is fibrous because of old tuberculosis, the remainder does not appear to be. There are no blebs. The heart is definitely enlarged. The supposition that the enlargement was right ventricular is, however, based on fluoroscopy.

DR. MEANS: Is there any reason to give up that idea?

DR. HAMPTON: None at all.

DR. MEANS: It seems to me that the high venous pressure, the cyanosis, the right-sided enlargement, the electrocardiogram showing right-axis deviation, and the engorgement of the pulmonary arteries by x ray studies, indicating high arterial pressure in the pulmonary artery, all fit the interpretation of this case as one of chronic cor pulmonale. The upper mediastinal pressure syndrome I should be inclined to give up because we have not found, by x ray or other examination, evidence of anything that could produce upper mediastinal pressure. Why only the upper half of the body was cyanotic, I cannot explain. Frankly, that puzzles me a good deal.

Why did the patient have cor pulmonale, and did he have anything else? I should like to throw in, not as a diagnosis but just by way of discussion, an idea that occurred to me as I went over this history. One of the conspicuous symptoms was paroxysmal dyspnea. One usually finds paroxysmal dyspnea in hypertension. This man was hypotensive. He had these paroxysms of dyspnea, and I do not believe that they were asthmatic because there is nothing to go with that. The low blood pressure, the prostration and the paroxysms of dyspnea are very impressive, and they make me think of an adrenocortical insufficiency, particularly since the last came on at a time when the patient did not have other cardiac symptoms, and I remember being told by one of my teachers that he had seen very striking paroxysms of dyspnea in Addison's disease. I looked through several textbooks of medicine and could

find nothing whatever about it. The Addisonian crises that are somewhat like shock are described, but nothing is said about paroxysmal dyspnea. I therefore called my teacher on the telephone,—it was Dr. William H. Smith,—and he said, "You are entirely correct; I have seen Addison's disease with symptoms of severe attacks of paroxysmal dyspnea." He said that Dr. George Sears had also seen it and had told him about it. I cite them as authorities that in Addison's disease one does get paroxysmal dyspnea. I am not prepared to say that this patient had Addison's disease, but I shall be interested in what is found in the adrenal glands, and if anything is found there pathologically I shall be satisfied; if it is not, I shall not be disappointed, because it is a long shot.

How can we put these findings together on one etiology? The tabes was due to syphilis, of course. Could the rest of it have been due to syphilis? Well, it could. Cor pulmonale occurs in Ayerza's disease, which is a type of syphilitic endarteritis of the pulmonary vessels. That is a possible explanation. It is also stated in the textbooks that sometimes syphilis affects both adrenal glands and produces adrenocortical insufficiency or Addison's disease, so that syphilis probably could explain everything except the peripheral neuritis, which is explained by the antisiphilitic treatment. However, we know that the patient also had tuberculosis,—we have evidence by x-ray examination and by the history,—and that he had been running a fever; the high white-cell count could have been due to active tuberculosis. Dr. Paul D. White,\* in his book, does not mention tuberculosis as a primary cause of cor pulmonale, but he does mention fibrosis. I suppose that tuberculosis produces fibrosis of the lungs; it certainly causes fibroid phthisis. This patient apparently did not have a serious enough process to cause cor pulmonale, but this is definitely a recognized possibility. Dr. White also mentions pneumoconiosis and silicosis as giving rise to fibrosis, which could produce cor pulmonale. I do not know that this man had any such exposure, so that I do not know which etiology is most likely here. We can explain everything on one etiology if we say this was syphilis, but on the doctrine of chances it is somewhat more likely to be on a tuberculous basis. I therefore summarize by offering as diagnoses, with a certain amount of trepidation: tabes, old and inactive; arsenical peripheral neuritis, with toe drop—I do not know if he still had it at the last entry because they did not mention a neurologic

examination; cor pulmonale, with congestive failure the cause of death; some form of pulmonary fibrosis, possibly, adrenocortical insufficiency, more likely due to tuberculosis than to syphilis. I do not believe that one need mention cancer, although the adrenal glands are sometimes involved by a malignant process. I cannot find any evidence of cancer, so I think that it can be ruled out.

DR. DONALD KING: I saw this man in consultation with Dr. Kite. On the basis of this first film, as Dr. Hampton said, I thought he probably had enlarged lymph nodes at the hilus. I sent him in with the idea that it might be lymphoma and that x-ray treatment might relieve the pressure.

I do not believe that the cyanosis of the upper part of the body, as distinguished from the rest of the body, was very marked.

DR. TRACY B. MALLORY: Sometimes, in simple cases of emphysema, it is more marked in the upper half of the body than in the lower half; I do not know why.

DR. KING: The roentgenologist who went over the films and did the fluoroscopy said that the shadows were pulmonary arteries and not lymph nodes, and that settled that. Then the question came up concerning the condition in the vascular bed in the lungs. Experience has shown that it is difficult to distinguish between plain pulmonary arteriosclerosis without narrowing of the lumen, obliterating endarteritis and thrombi. Dr. Bland saw this man in consultation. I forget which of these diagnoses he chose, but I think that it was obliterative endarteritis.

DR. EDWARD F. BLAND: I chose that, but I think we overlooked the leukocytosis and the paroxysms that Dr. Means has brought out. I might say that we saw him just before he died, and we did not have quite the problem that Dr. Means had in dealing with the past history. He was a very ill man, with obviously extreme cor pulmonale, distended neck veins, congested liver and the x-ray findings described; when it was all added up, we chose between two possibilities—obliterative endarteritis and thrombi.

DR. KING: The patient probably did not have pulmonary fibrosis from the x-ray standpoint.

DR. HAMPTON: I do not believe he had enough to produce cor pulmonale. It is chiefly confined to the upper lobes. The lower lobes are very good. The change in the bases of the lungs over a period of a month are further evidence that the process was more acute.

DR. PAUL D. WHITE: What was your second choice, Dr. Bland,—thrombosis of the pulmonary vessels based on emphysema?

\*White, P. D. *Heart Disease*. 931 pp. New York: Macmillan Company, 1931. Pp. 404-409.

DR. BLAND: We could not find any source for emboli.

DR. HAMPTON: These shadows are quite like those of pulmonary infarcts.

DR. WALTER C. KITE: I think it has not been emphasized that all the neurologic symptoms were unilateral, all on the right side. The cyanosis and the dilatation in the neck did not develop until five days before death. This man was in the office at work one week before Dr. King first saw him.

DR. KUBIK: When this patient was studied here, about three and a half years before he died, a presumptive diagnosis of *tabes dorsalis* was made. At that time, there was not much weakness. The patient had been complaining of numbness or paresthesia, and there was some analgesia, as well as impairment of vibratory and position sense. The Argyll-Robertson pupils influenced us a great deal, as they did Dr. Means. The later course, marked by the development of foot drop, and the marked weakness, with some atrophy, did not fit in with *tabes*. I believe that the patient was seen later at the Boston City Hospital, where a diagnosis of peroneal muscular atrophy was made. When he was here, we did think of the possibility of hypertrophic interstitial neuritis, but could not find any hypertrophy of the peripheral nerves and concluded it probably was not that.

#### CLINICAL DIAGNOSES

Pulmonary endarteritis.  
Cor pulmonale.  
Heart failure, right-sided.  
*Tabes dorsalis*?

#### DR. MEANS'S DIAGNOSES

Chronic cor pulmonale.  
Congestive failure, right-sided.  
Pulmonary fibrosis (<sup>2</sup> type).  
*Tabes dorsalis*, old.  
Arsenical neuritis, old?

#### ANATOMICAL DIAGNOSES

Degeneration of spinal-nerve roots.  
Secondary degeneration of posterior columns.  
Thrombosis, left popliteal vein, old.  
Embolism and thrombosis of pulmonary arteries, old and recent  
Cor pulmonale.  
Infarcts of lungs, healed.  
Chronic passive congestion  
Ascites.  
Pulmonary tuberculosis, inactive.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: The post-mortem examination showed a considerably enlarged heart; nearly all the enlargement was on the right side, the right ventricle was nearly twice as capacious as the left, and in spite of the dilatation, it measured 7 mm. in thickness. The pulmonary arteries showed clots of all ages, some quite fresh and some evidently very old, completely organized and extensively recanalized. These were present in the major and intermediate-sized arteries, and the small arterioles throughout the lung were entirely normal. The picture suggested to us multiple embolism, with perhaps secondary retrograde thrombosis and primary pulmonary endarteritis. As a possible source for this, there was an extensive old thrombophlebitis of the left iliac vein. Will you continue with the neurologic findings, Dr. Kubik?

DR. KUBIK: There was marked degeneration of the calf muscles, presumably secondary to disease of the anterior spinal roots or of the spinal roots and anterior horn cells. Both anterior and posterior spinal roots of the cauda equina were enlarged. Many of them were two or three times the normal size. Microscopic sections showed that the enlargement was due to interstitial tissue; the fibers were actually diminished in number. The remaining ones were in process of degeneration. There was degeneration in the posterior column, which, I should say, was secondary to degeneration of the posterior roots. I am not altogether sure about the findings in the anterior-horn cells. Many of them exhibited changes that were unquestionably secondary to the degeneration of the anterior roots (axonal reaction), but I could not be sure that there was not also some primary degeneration. It will require further study to establish a diagnosis. Peroneal muscular atrophy (Charcot-Marie-Tooth disease) is a possibility, and perhaps hypertrophic interstitial neuritis also has to be considered, even though there was no hereditary or familial history.

DR. MEANS: What were the Argyll-Robertson pupils due to?

DR. KUBIK: I cannot answer that. The mid-brain has not yet been examined.

DR. MEANS: Did your neurologic examination exclude ordinary *tabes*? You told us that you did not know what to call it, but can you say it is not *tabes*?

DR. KUBIK: Almost certainly not. In *tabes*, the anterior roots are of normal size, and the posterior roots are very small.

DR. MEANS: Was there any evidence of tuberculosis?

DR. MALLORY: There was inactive apical tuberculosis, not progressive.

DR. MEANS: Were the adrenal glands normal?

DR. MALLORY: Yes.

### CASE 28092

#### PRESENTATION OF CASE

*First admission.* A sixty-three-year-old housewife was admitted to the hospital because of a fainting spell.

She had suffered recurrent episodes of abdominal pain for many years. These attacks, which were described as crampy, colicky and associated with "gas," started in the left upper quadrant, and occasionally radiated over the lower ribs or down the left arm and to the left subscapular region. The pain was never substernal. There was no nausea or vomiting, and the bowels had always been regular. In the year before entry, the discomfort seemed to follow exertion, although this was not always so. The patient was able to relieve the pain by raising or swinging her arm, or by taking nitroglycerin. At times, she took bismuth and restricted her diet, and passed several weeks without pain. On the evening of admission, an attack came on while the patient was attending a concert. She took a tablet of nitroglycerin, and shortly afterward fainted.

The family history was irrelevant, and the past history complicated. The patient had had severe varicella when thirty-nine years old. At forty-one, she had had the uterus removed for prolapse. Two years later, the gall bladder had been removed for "pain"; gallstones were found at the operation. Hemorrhoids were removed at the age of fifty-one, yet the patient noted occasional bright-red blood in the stools in the year preceding entry. Eight months before admission, roentgenographic examination, including a barium enema and a gastrointestinal series, showed "diverticulosis of the large bowel."

Physical examination showed an obese woman in no distress. The chest showed evidence of old rickets. The heart was of normal size, with a very soft systolic murmur of the apex, and a loud, ringing aortic second sound. The lungs were clear. There was slight, diffuse tenderness in the abdomen, most evident in the left upper quadrant. The liver edge was palpable one or two fingerbreadths below the costal margin.

The temperature was 97°F., the pulse 75, and the respirations 24. The blood pressure was 160 systolic, 90 diastolic.

Examination of the blood showed a white-cell count of 5900. The urine showed a + test for

albumin, with 50 white cells per high-power in the sediment.

An electrocardiogram showed sinoauri bradycardia, with a rate of 50. The P waves PR intervals were normal. There was slight ring of the QRS complexes, and marked left deviation, with inversion of all complexes Lead 3.

The patient was discharged on the second

*Second admission* (nine months later). Six months after discharge, the patient fell down and fractured her left shoulder. Because of injury, she lay on her right side frequently, a position that seemed to bring on the customary attack of abdominal pain. A month later, the left ankle was broken in another fall. A month after this, one of the episodes of abdominal discomfort was followed abruptly by radiation of tearing "tearing" pain downward over the whole left into the pelvis. The patient felt nauseated, dizzy, and vomited. There were no chill or fever. Nitroglycerin afforded no relief. After an hour and a half, a physician gave her a hypodermic injection. The severe pain went away gradually within half an hour, but an ache was then noted in the arms below the shoulders. There was gradual onset of numbness and weakness in both legs, progressing to anesthesia, paralysis within two hours. The patient was able to urinate or defecate. In retrospect, the patient stated that her left leg had seemed colder than the right for several months before this attack.

On re-examination, the patient again appeared in no acute distress. The heart and lungs were essentially as before. The abdomen was distended. The liver edge lay two to three fingerbreadths below the costal margin. There was total loss of sensation in the lower extremities and abdomen below a level corresponding approximately to the level of the insertion of the diaphragm. The upper limit of this area of anesthesia shaded off gradually rather than sharply. The skin over the region involved was of normal color. Voluntary movements of the lower extremities were abolished. Deep tendon reflexes and abdominal reflexes were absent. Stimulation of the soles of the feet produced slow mass flexion and extension reflexes in the whole lower extremities.

The temperature was 100.5°F., the pulse 110, and the respirations 20. The blood pressure was 110 systolic, 60 diastolic, in each arm.

Examination of the blood showed a white-cell count of 9200 with 83 per cent polymorphonuclear cells, and a red-cell count of 4,000,000 with 15 gm. hemoglobin. The serum protein was 5.5

per 100 cc. The urine showed a + test for albumin, with occasional red cells in the sediment.

An electrocardiogram was quite similar to that obtained on the first admission, except for increase in amplitude of T<sub>2</sub> and T<sub>3</sub>, without, however, any characteristic shape.

A roentgenogram of the thoracic spine showed no evidence of vertebral disease. The entire thoracic aorta was tremendously enlarged. The aortic knob, 10 cm. in diameter, displaced the trachea toward the right. There was calcification in the inferior rim of this knob, and a line of calcification in the wall of the descending aorta, lying well out toward the axillary line. The heart shadow showed prominence in the region of the left ventricle. The lung fields were clear.

Lumbar puncture yielded clear colorless fluid under initial pressure of 145 mm. Microscopic examination showed 454 red cells and 1 white cell per cubic millimeter. The total protein was 52 mg per 100 cc. The gold sol curve was 1233411000. There was insufficient fluid for a test of the Wassermann reaction.

On the second hospital day, the temperature fell to 98°F, and the pulse and respirations continued as before. The patient felt prickling in the legs and feet, especially on the right, but there was a slow further return of protopathic sensation. Bilateral Babinski plantar responses gradually appeared. Subsequent roentgenograms of the chest showed essentially no change. From time to time, there were transient elevations of temperature to 100°F. Tidal drainage of urine by catheter was maintained. There was intermittent bacilluria, which responded fairly well to sulfadiazine therapy. The patient was discharged after ten weeks, unimproved.

At home, the slow return of sensation continued, but there was no return whatever of motor control. The patient continued to have frequent bouts of pain, which appeared to originate in the left upper quadrant but radiated to the region of the left scapula and, on one occasion, to the right shoulder. The pain was often severe enough to make her break out in a perspiration. It could sometimes be relieved by lying on the left side. Relief from the pain was sometimes accompanied by an audible gurgling in the left flank. Two months after discharge, the patient awoke one morning with severe knifelike pain about her left shoulder and under her left scapula. She felt faint and vomited. The pain was gradually relieved after a hypodermic injection of morphine. In the late afternoon of the same day, the pain returned, and the patient rapidly went into severe shock and gradually became comatose. She died five hours after this second attack of pain.

## DIFFERENTIAL DIAGNOSIS

DR FRANCIS R. DIEUAIDE. We have an elderly woman who had two sets of attacks of pain. One of these comprised colicky pain, which radiated usually into the left upper arm and to the left shoulder and was said to have been present for many years. There were two major episodes of extreme pain, the first of which is described as "tearing," along the left side down to the pelvis. It grew out of one of the attacks of the previous series. It was associated with paraplegia. The second attack was knifelike pain about the left shoulder and under the scapula, followed by death in five hours. These two discrete attacks strongly suggest pain of vascular origin. We also know that there were marked changes in the vessels in the x-ray picture. As to the paraplegia, we are given no sign of interference with circulation in the legs. On the whole there is little doubt that the difficulty was of cordal origin. There were two recent fractures. The question might be raised whether they were pathologic fractures and whether the patient had a neoplasm somewhere, but there is no evidence of that and we are directly told that there was no sign of fracture in the vertebral column. I suppose one should also raise the question whether the difficulty might have been due to metastases in the cord itself, but there is no reason to think of that in the face of the other information; furthermore, we must note the improvement in sensory function, which apparently was quite good, although there was no return of motor function. Everything considered, I think one might easily come to the conclusion that these cord changes were probably due to a vascular disturbance. The two major attacks of pain might possibly suggest coronary pain—associated with myocardial infarction, perhaps; but the description is somewhat peculiar, especially the radiation in the first attack to the pelvis. Such radiation happens occasionally, although rarely. Coronary difficulty offers no explanation for the cord changes. The blood pressure was well sustained, although it did fall somewhat. The electrocardiogram was normal, except for sinoauricular bradycardia. This is very much against a diagnosis of coronary occlusion with myocardial infarction.

An aneurysm of the ordinary vascular sort might possibly account for the recurrent pain, but I do not believe that such an aneurysm could account for the two discrete attacks described. We have no evidence for syphilitic aneurysm, no positive blood or cerebrospinal fluid Wassermann reaction. The spinal fluid was essentially normal. It was contaminated with a little blood, but that is enough

to produce the gold-sol changes, even though the fluid was colorless.

Of course, this might have been an arteriosclerotic aneurysm; the patient was an elderly woman, and that is a possibility. Furthermore, the calcification in the x-ray pictures speaks directly for that because calcification of that sort is not likely to be present in syphilitic aortitis. The blood pressure speaks somewhat for an arteriosclerotic process. Then we have dissecting aneurysm. The description of the first attack fits very well, I think, into the usual description of dissection, although arm radiation is not nearly so common as it is in myocardial infarction. It is, however, described in some cases; I do not believe that it is against the diagnosis. The maintenance of blood pressure is in favor of it, and the cord changes are particularly in favor of it.

May we see the x-ray films?

DR. TRACY B. MALLORY: There is no radiologist present.

DR. DIEUAIDE: I hesitate to say just what this shadow is, but it is evidently the outline of a vascular swelling of some sort, derived from the aorta and extending far to the left. I doubt if, at a distance, one can see the calcification, but there is a good deal of it spread out in a large semi-circular arc well to the left of and below the usual site of the aortic knob. With these x-ray films, in addition to the story, one would, I think, be going out of the way not to concentrate on dissecting aneurysm.

In recent years, we have heard a great deal about dissecting aneurysms in aged people, more commonly perhaps in men, but still not rarely in women. The dissection frequently occurs after exertion, but not necessarily. It is sometimes symptomless, a double aorta being found only by post-mortem examination. The blood pressure is usually relatively maintained in patients who do not succumb. I am inclined to think that this patient had dissection of the ordinary type, based on media necrosis cystica.

The cord changes are of special interest in connection with dissecting aneurysm, if we are right about the diagnosis. They have been recently emphasized by Tuohy et al.,\* who stressed the patchy, transient character of the symptoms, and the frequent occurrence of coldness and numbness. The changes described here are severer. We are interested especially in the persistent, complete loss of motor function. I have no explanation for that. I am sure that someone else will be able to tell us about the circulation of the lower cord. As I understand it, it is a little more vulnerable

than circulation of the upper cord, because blood is supplied to the upper part by the vertebral arteries, whereas the lower cord has only the branches of the aorta, the intercostal and sacral arteries. If this diagnosis is correct, the lesion should have extended down into the abdomen so that it cut off the blood supply of the lower part of the cord. At the same time, other vessels might have been affected, such as the renal artery. We have no particular evidence of that in this case.

The second attack of pain on the last day speaks for rupture of the dissection. Dissection usually begins in the upper mediastinum. If the patient had a dissection, since there was pain about the left scapula, I should first think of the mediastinum as the site of the rupture.

The preceding series of attacks offer me some difficulty. The attacks for many years were centered in the left upper abdomen, a somewhat unusual site. Did the patient have diverticulosis? In any event, I do not think chronic diverticulitis is a likely explanation. The gurgling that occurred when the patient had relief of pain does not mean much to me. The pain might suggest a second serious lesion, such as carcinoma of the colon but this is unlikely. I suppose one should mention diaphragmatic hernia. The pain is quite permanent for that, and we ought to be able to see a hernia in the x-ray film. The patient apparently acquired a urinary-tract infection, but these attacks do not sound much like renal pain. The radiation was upward instead of downward, as it usually is in renal pain. Were they attacks of anginal pain? The reasons mentioned before are still against that. Relief by nitroglycerin does not prove anything. Relief by swinging the arm is also rather against angina. I think that the patient must, of course, have had an antecedent aneurysm before the dissection, an unusually large one to be caused by atheroma. Somehow, these attacks of pain were produced by this aneurysm which I should guess to have been in the first portion of the descending thoracic aorta. So that I think the patient had the following conditions: an old arteriosclerotic process with hypertension although there is not much evidence of that, and an unusually large arteriosclerotic sac—perhaps. I am passing up a chance to make a diagnosis of syphilitic aneurysm, but I do not believe so; a dissecting aneurysm, which went all the way to the neighborhood of the bifurcation of the aorta but not through it; and something like myelomalacia of at least the lower spinal cord, which seems to have affected the pyramidal tract particularly. I suppose there was also cystitis and perhaps pyelitis.

DR. WILLIAM B. BREED: It is strange that no

\*Tuohy, E. L., Boman, P. G., and Berdez, G. L. Spinal cord ischemia in dissecting aortic aneurysm. *Am. Heart J.* 22:305-313, 1941.

serologic findings are recorded. I should be interested in knowing what they were.

DR. MALLORY: There was no record of them. The patient's physician checked over his records and also corresponded with other doctors who had seen her. I think it was one of those cases in which each one assumed that the other had done it.

DR. EDWARD F. BLAND: This patient's history and x-ray films were presented at Grand Rounds in the Ether Dome. Some of you may recall it. Dr. Michelsen discussed the cord difficulty. At the time, all were quite convinced that this must be a dissecting aneurysm or some modification of it. I think there was only one dissenting voice, and that was from the pathologist who was present — Dr. Castleman. He wondered if the size of the aorta by x-ray study did not suggest the likelihood of something else than a simple dissection. There were one or two other interesting points that Dr. Castleman raised about the presence of calcification of the aorta. Perhaps he would comment on that now.

DR. BENJAMIN CASTLEMAN: We had never seen a dissecting aneurysm in the presence of marked arteriosclerosis and calcification. Also, the patient did not have hypertension. Although dissecting aneurysms have been recognized on x-ray examination, they do not produce such marked dilatation of the aorta as was seen in this patient.

A PHYSICIAN: I had seen her for three years, and she never had a systolic blood pressure over 160 during that time.

DR. MALLORY: The great majority of the cases that we have seen have had a definite hypertension. One case of Dr. Fremont-Smith's that we presented recently had very little, however.

DR. JOST MICHELSEN: There was little doubt from the onset that the cord lesion was a vascular affair, and the dynamics during lumbar puncture were quite normal. The return of sensation was really very slight — practically none at all. I wonder why Dr. Dieuaide used the term "contamination" of the cerebrospinal fluid. Four or five hundred red cells may be found in cases of vascular obliteration, and are consistent in this case with arterial occlusion, which caused the softening of the cord.

#### CLINICAL DIAGNOSES

Dissecting aneurysm, with apoplexy of cord at the fifth dorsal segment.

Obesity.

Diverticulosis.

#### DR. DIEUAIDE'S DIAGNOSES

Extensive atheroma of aorta, with aneurysm.

Dissecting aneurysm.

Myelomalacia of lower spinal cord.

Cystitis or pyelitis?

#### ANATOMICAL DIAGNOSES

Aneurysm of descending aorta, probably syphilitic, with rupture.

Hemothorax, left

Arteriosclerosis, severe, aortic and coronary.

Infarction of spinal cord.

Operative scars: cholecystectomy and hysterectomy.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: At post mortem examination, a very large fusiform aneurysm of the descending aorta was found. It began just beyond the arch and extended nearly down to the diaphragm. It was filled with a laminated thrombus, which appeared to cover the mouths of the intercostal arteries; it seemed rather surprising that more of them were not obstructed. The aneurysm had ruptured into the left pleural cavity, which contained about 1500 cc. of blood, and the lung on that side was totally atelectatic. There was no dissection. The question then arose whether this was an arteriosclerotic, senile aneurysm or a syphilitic aneurysm. We have no serologic findings to bear on the point, so that we have nothing to go on but the microscopic appearance of the aorta itself. I do not believe that all members of the department are entirely unanimous as yet, but as I studied it I should have to call it syphilitic. There were marked focal destruction of the elastica in the media, collars of lymphocytes around the vessels in the adventitia, and sizable collections of plasma cells in the adventitia, which I should take more seriously. The ascending aorta was absolutely smooth and normal, and that is unusual in cases of syphilis. Sections of the ascending aorta were entirely normal. If I had to make a decision on the case, I should vote for syphilitic aneurysm. Dr. Kubik will tell us about the cord.

DR. CHARLES S. KUBIK: There was a softening of the cord, beginning at about the fifth thoracic segment and extending down into the midthoracic region. The lower part of the cord was normal.

The cord receives its blood supply from two sources: from the anterior spinal artery, which branches from the vertebral arteries, and from branches of the intercostal arteries. The anterior spinal artery did not provide an adequate blood supply in this case when the intercostals were blocked off by the lesion of the aorta. I do not recall another case like this.

DR. MALLORY: There was enough sclerosis in the coronary arteries for the patient to have had angina. The other possibility is that the attacks of colic were tabetic crises.

## PROCUREMENT AND ASSIGNMENT SERVICE

In these times of stress, physicians, as well as everyone else, are considering how they can best serve the Nation, and from the point of view of medical service, many factors must be taken into account. There seems little doubt that eventually nearly all male physicians under forty-five years of age who are physically and educationally qualified to enter military service will be inducted, but due regard must also be paid to the medical needs of other governmental agencies, state, county and municipal institutions, nongovernmental hospitals, medical schools, industry and, last but not least, civilian communities.

With all this in mind, the House of Delegates of the American Medical Association, at its meet-

ing in Cleveland last June, recommended to the Government that a procurement and assignment agency for physicians be formed, and on October 31, 1941, the creation of the Procurement and Assignment Service for Physicians, Dentists and Veterinarians, a subdivision of the Office of Defense Health and Welfare Services of the Office for Emergency Management, was authorized by the President. This agency is specifically instructed "to receive from various governmental and other agencies requests for medical, dental and veterinary personnel, to secure and maintain lists of professional personnel available, showing detailed qualifications of such personnel, and to utilize all suitable means to stimulate voluntary enrollment, having due regard for the overall public health needs of the Nation, including those of governmental agencies and civilian institutions." In accordance with the suggestion of the House of Delegates, the Directing Board is composed of five civilian practitioners,—four physicians and one dentist,—the chairman being Dr. Frank H. Lahey, of Boston, president of the American Medical Association.

Owing to the proximity of the creation of the Procurement and Assignment Service and the declaration of war on December 8, the bare skeleton of the necessary working force of the central office in Washington had only been established when it was flooded with requests for personnel from the military services and governmental agencies and for information from physicians, dentists and veterinarians. The demand for personnel resulted in an appeal for physicians who were immediately available for military service, and the response was so satisfactory that these needs have been met. It has been impossible, however, to answer the letters requesting information, and the Directing Board of the Procurement and Assignment Service decided that all existing pertinent facts should be made available to physicians, dentists and veterinarians. Much of this material has appeared from time to time in the *Journal of the American Medical Association* and the state medical journals; but there has been little continuity, and many of the basic regulations have subsequently been changed. Hence, the article in the February 21

issue of the *Journal of the American Medical Association* that describes the functions and activities of the Procurement and Assignment Service, gives recommendations based on current regulations and furnishes additional miscellaneous information should be carefully read by all members of the medical profession

Subsequent planning for the provision of military personnel and for the protection of nonmilitary medical services demands more facts than are now in the hands of the Procurement and Assignment Service, which consist chiefly of data taken from the questionnaires sent out by the American Medical Association over a year ago. State, district or county and local committees must prepare lists of essential personnel, which are based on the needs of industry, medical schools, hospitals and communities. But what is even more important, exact up to date information concerning the status of all physicians must be obtained. Within a few weeks, the Procurement and Assignment Service will forward a questionnaire to every physician, dentist and veterinarian within the United States. Furthermore, this will be accompanied by an enrollment form, whereby the physician, dentist or veterinarian, by signing up with the Procurement and Assignment Service, can express his willingness to help in the present emergency and can indicate his preference for service.

When the questionnaire is received, *all registered physicians, regardless of age, sex, physical condition, educational qualifications and citizenship, should immediately fill it out and return it*. Enrollment is purely voluntary, but in view of the criticalness of the war situation, it is difficult to comprehend how any physician can fail to offer his services to his country—ENROLLMENT SHOULD BE ONE HUNDRED PER CENT!

## EXAMINATION OF SELECTEES

UNTIL very recently, selectees have been examined by physicians of the Selective Service boards and, if

classified by them as fit for general military service, have been sent within a few weeks to an induction center, whose physicians work directly under the supervision of the Army of the United States. Selectees were sent to the induction centers on the assumption that they were physically and mentally fit and that they would be immediately sworn into the Army and sent to camp. Unfortunately, this was not the case. Approximately 18 per cent of the men were rejected because of the findings of the examiners at the induction centers, yet these men had had, perforce, to give up the positions in which they were employed and returned to their homes without a job and marked, in a way, as unfit. Furthermore, employers did not always distinguish between ability to hold down a civilian job and that to stand the rigors of combat service.

This has all been changed—and for the better. Selectees are examined by their local examining boards only for "gross disqualifying defects." If none are found, the men are, at some later date, sent to an Army examining or induction center. If they are then found to qualify fully for "general military service," they are returned to their homes with such knowledge and with the opportunity of rearranging their affairs before being called to camp some weeks later. If rejected, the causes of their defects are explained in simple language, and they are admonished to consult their personal physicians, if there is such a need. The burden on the Army physicians is, of course, greater, and their task more difficult, but the local board physicians—who generously donate their services—are relieved of much responsibility, and the selectee is in a far better position to arrange his own private affairs, come what may.

It is further hoped that some form of rehabilitation may find its way, officially, into this program. There are thousands of men with remediable defects who could, with appropriate aid, become fit for general military service and, by the same token, even better qualified to carry on in civilian life. Such rehabilitation is at present voluntary. It may and should become compulsory.

## OBITUARY

## KENNETH DANIEL BLACKFAN

1883-1941

Kenneth Blackfan began his career in medicine in the year 1905 as a country doctor. Eighteen years later he became Thomas Morgan Rotch Professor of Pediatrics, and for another eighteen years he carried his department forward with consummate skill and success. There is no need to recount to this faculty his large services to the Harvard Medical School. But, in order that our admiration of him may be complete, the record of a continuous and hard-won education which brought the country practitioner to a position of high effectiveness in university medicine should be before us.

He was born and spent his boyhood in Cambridge, New York, a pleasantly situated hamlet about forty miles north of Albany. On graduating from the local high school, he entered the Albany Medical School of Union University. During his third year, Richard Pearce came to the school as professor of pathology and bacteriology. Kenneth Blackfan responded to the enthusiasm of this fine student of disease. He begged, and won, permission to work in his laboratory through the following summer. A warm student-master friendship sprang up. This friendship determined his future course in medicine. But not immediately. On receiving his medical degree at the age of twenty-two, he returned to his home town and for the next four years drove about the countryside on the varied errands of a general practitioner. He always recalled those horse-and-buggy years with pleasure, and there are older citizens of that region who still delight in relating therapeutic triumphs of "young Doctor Ken." But there were disturbing visits to nearby Dorset, just over the line in Vermont, where Richard Pearce spent his summers. There he found friendly interest and encouragement, which gradually produced the determination to find out what might lie over the horizon in medicine.

So, in the year 1909, the young country doctor set out for Philadelphia with letters from Richard Pearce. There he was kindly received by Samuel Hamill and David Edsall, and a place was soon found for him as resident-in-charge of a foundling hospital. Kenneth Blackfan thereupon became a pediatrician. Two years later, John Howland, who had accepted the professorship of pediatrics in the newly reconstructed medical school of Washington University, offered him a residency. This was a very large stroke of fortune. It removed the adventurer from his lonely post in the foundling

hospital and, after two years in St. Louis, placed him in the group of young pediatricians who assembled around Howland in Baltimore when he succeeded Von Pirquet at Johns Hopkins in the year 1912. Here there was a newly built hospital for infants and children, and laboratory equipment far beyond anything which had yet been given a clinical department in this country. Howland's group used their large opportunity with enthusiasm, and under his wise guidance, the laboratories were from the outset importantly productive. It was the place to be in pediatrics at that time. The most beloved member of this group was the resident physician. No one watched work under way in the laboratories with a more eager interest. And he found time to participate. By way of instance, his work with Dandy on internal hydrocephalus has come to deserve that lofty adjective, classic. His demonstration that dehydration is a much more dangerous feature of diarrheal disease than is the state of acidosis, which Howland and Marriott had just discovered, shifted emphasis from alkali therapy to fluid replacement and produced the basis of our present effective treatment of this chief scourge of infants.

When Kenneth Blackfan reached the age of thirty-seven, he was still a resident. He had held this modest post for eleven years. But he had reached his goal. He knew the existing body of knowledge in his chosen field, he knew its frontiers, and he knew where the paths of progress lay. He was a superb diagnostician and a master of detail of hospital care of patients. Behind all this, four years of countryside practice had given him resourcefulness in use of means at hand and an understanding of the social realities of the physician's task. He was in all respects qualified for the diverse duties of departmental headship. His first commission came in the year 1920, when he was appointed professor of pediatrics at the University of Cincinnati. There he built up his department and guided a large development of hospital equipment with outstanding success. Then in 1923 the fruits of eighteen years of education toward leadership fell to Harvard.

Why did he follow this long and economically narrow path with such serene contentment? This question would have annoyed Kenneth Blackfan. His philosophy was remarkably uncomplicated. There was nothing which could be called ambition, and there was nothing of the *ich dien* complex about him. He had simply discovered a durable delight in his work. The anatomy of this delight did not interest him. He knew an inscrutable phenomenon when he saw one. His modest and conservative use of a fine mind gave

his judgments a great validity and brought him into a high position in the councils of this school. Knowing little of the art of verbrige, he was not a skillful lecturer, but in the wards his teaching of students and of interns was close to perfection. He used the treasures of his experience, not to dazzle by making the diagnosis at a glance, but to point out sound appraisement of obtainable evidence.

A large cause of Kenneth Blackfan's success in leadership was his gentle friendliness. He always made his associates feel that they were his comrades in the enjoyable adventure against disease. Also, he was very brave. Beginning in his later Baltimore years, he suffered a series of physical afflictions which he bore with an unbelievable fortitude. He was friendly and gentle and brave. The simplicity and the sincerity of these traits gave him his great beauty of personality.

R M S

A resolution adopted by the Faculty of the Harvard Medical School, January 7, 1942

\* \* \*

Kenneth Daniel Blackfan, Thomas Morgan Rotch Professor of Pediatrics at the Harvard Medical School, chief of the Medical Service of the Boston Children's Hospital, medical director of the Infants' Hospital, wise counsellor to many, was born in Cambridge, New York, in 1883, the son of a country doctor. He was graduated from the Cambridge High School in 1901 and from the Albany Medical School of Union University in 1905, and after this minimal amount of formal education, became himself a country practitioner. From this realistic postgraduate course in the art of medicine, he emerged four years later, *summa cum laude*.

Turning his back at this point on general practice, he became resident in-charge at the St Vincent de Paul Foundling Hospital in Philadelphia, then resident pediatrician at the St Louis Children's Hospital, then, in 1912, resident pediatrician at the Harriet Lane Home and instructor in pediatrics at Johns Hopkins University School of Medicine. He was still at this post, in 1917, when the first world war stripped the country of its physicians. His associates left him, even to his chief John Howland, he himself was an officer in the Medical Reserve Corps but, afflicted with corneal ulcers following a Gasserian ganglion operation, was, of necessity, released from military service.

'They also serve who only stand and wait'  
Kenneth Blackfan remained in Baltimore and,

almost single handed, with the help of his students, carried the department and the Harriet Lane Home through the war years.

In 1917, he was made an associate and, in 1919, associate professor of pediatrics. The following year he became professor of pediatrics at the University of Cincinnati, where he remained until the call to his last post, with us, in 1923.

Labors fall in good measure upon willing shoulders, and Kenneth Blackfan bore his share of them uncomplainingly, and the honors that sometimes accompany them, unassumingly. Among other obligations that he accepted after coming to Boston were, in 1925, the presidency of this society and, for the three succeeding years, membership on its council.

After he had spent those years in the wilderness of private practice, with the intellectual diet of locusts and wild honey that accompanied them, his activities became more diversified, being divided among clinical, investigative and administrative medicine, always with teaching. It is with these four major activities in mind, but with his personality in the foreground, that we do honor to him now and record these simple facts.

A good tree cannot bring forth evil fruit, neither can a corrupt tree bring forth good fruit.

Wherefore by their fruits ye shall know them

Matthew VII 18-20

J G

A resolution adopted at a meeting of the New England Pediatric Society on January 14, 1942

## MEDICAL EPONYM

MURPHY BUTTON

On October 15, 1892, Professor John Benjamin Murphy (1857-1916) read his first description of this article before the Mississippi Valley Medical Association, and the paper appeared under the title Cholecysto-intestinal, Gastro-intestinal, Enterointestinal Anastomosis and Approximation without Sutures (Original Research) in the *Medical Record* (42: 665-676, 1892).

To overcome these obstacles and thus lessen the risk to the life of the patient, I have devised a mechanical means to dispense with the need of sutures the necessity of invagination the possibility of non apposition the sloughing through of disks the digestion of the catgut, the almost unsurmountable difficulties of technique of operation, the prolonged and fatal exposure of the abdominal contents and the protracted anastomosis. How much I have accomplished by my labor I desire you to be the judges after I have demonstrated to you the results of my experiments and performed for you a gastroenterostomy and an end-to-end approximation of intestine by means of the device I here present to you to be known as the Anastomosis Button.

R W B

## MASSACHUSETTS MEDICAL SOCIETY

## COMMITTEE ON MATERNAL WELFARE

## OBSTETRIC ROUTINES

No one can tell how seriously the national emergency will influence hospital nursing, but much of the refinement that has come to be regarded as necessary will have to be eliminated. It is not at all unlikely that many obstetric services will very seriously feel the shortage of nurses; however, if well-trained and efficient head nurses can be retained, such services can be staffed by younger and less experienced nurses. If this situation eventuates, and something of the sort undoubtedly will, the fewer drugs there are in the medicine cabinets the simpler their administration will be, and the fewer the mistakes made. Furthermore, such a policy will cut down on expense.

Laboratory investigation has proved that skin disinfection at the time of labor can no more adequately, or perfectly, be accomplished than by the use of ether and a 1 per cent iodine solution. The same combination has also been used for a long time, with perfect success, for preparation of the abdomen for laparotomy. The cost of this solution, depending on the market value of alcohol, is about 13 cents a pint. The formula of the solution is as follows: potassium iodide, 1 gm.; iodine, 1 gm.; and alcohol (95 per cent) up to 100 cc. The most economical way of applying the solution is to use a spray. A No. 15 DeVilbiss atomizer, with a nasal applicator, has proved to be satisfactory. For the preparation of the skin, when it is desirable to cause no discomfort, a watery solution of Zephiran is suggested. It is advised that no other solutions for skin disinfection be used in the delivery rooms.

The objection that iodine causes burns and so should not be used has been proved false, over a long experience, especially when such a weak solution is employed. Iodine may cause an occasional burn, but so may other skin disinfectants. Diabetic patients are said to have very sensitive skins; however, in a long experience with diabetic patients, no skin burn of any particular degree has occurred.

Because of the sensitiveness of the skins of some diabetic patients, the use of zinc oxide adhesive tape has been discontinued. Since in a large general hospital the use of zinc oxide tape, for the purpose of holding dressings on surgical wounds, must be a great expense in the course of a year, and since it is imperative that all savings be considered, it is suggested that this practice be discontinued. A gauze roll held in the stay sutures makes a satisfactory dressing.

Many preparations of ergot are on the market. If one standard preparation can be decided on for general use, it will make for a simpler, easier-running service. It is suggested that 1/320-gr. ampules of Ergotrate or Hypoloid Ergometrine be used intravenously and intramuscularly; these cost \$21.60 per hundred. Ergotrate or Ergometrine tablets, which cost about 4 cents apiece in thousand lots, are suggested as the sole ergot preparation to be used for oral administration. This routine has already been established in several hospitals in the Boston area.

It is also suggested that, because of the cost, thymol iodide *U.S.P.* be used solely in place of all other, and more expensive, dusting powders.

## RETIREMENT

Frank L. Morse, M.D., of Somerville, has recently retired after forty years' service with the Somerville Board of Health. He graduated from Harvard Medical School in 1894, and after three years at the Boston City Hospital, including two years as assistant resident physician at the South Department, was medical and sanitary inspector of the Massachusetts Board of Health from 1898 to 1905 and a district health officer from 1909 to 1915. From 1901 until his retirement from the Somerville Board of Health, he had been in charge of the bacteriologic laboratory, the contagious-disease hospital, contagious-disease control and all other medical work of the Board. He was discharged from active service in the United States Army in 1919, with the rank of lieutenant colonel, and was retired from the Officers Reserve Corps in 1935, with the rank of colonel.

## "CHILDHOOD ABDOMINAL SURGERY"\*

Not infrequently, when an abdominal operation is recommended for an infant or for a child, surprise is expressed by such a remark as, "I didn't know babies and children ever had such things," or doubt about the ability of the young to stand a surgical operation is indicated. So commonly are these ideas held that it has seemed wise to include some discussion of those conditions of the abdomen for which surgical treatment is desirable in the young.

The young differ from their elders in the frequency with which they are affected rather than in the types of their diseases. Thus, it has been stated correctly that the infant or child may present any of the surgical conditions recognized later in life, but that certain of them are very rare in the young and others are relatively common. The young differ also in their response to disease and may be prostrated seriously by an injury or infection sooner than adults would be. However, with appropriate treatment and management, their recuperative powers are tremendous, and their ability to heal and to repair damaged tissues is very great.

The first and most cheering point that I should like to make is that young persons are excellent surgical subjects, provided that the treatment is conducted by qualified surgeons, the hospital environment is adapted to the needs of infant and child, the anesthesia is well chosen and

\*A "Green Lights to Health" broadcast given through Station WAAZ by Dr. Henry W. Hudson, Jr., on December 6, 1941, and sponsored by the Public Education Committee of the Massachusetts Medical Society and the Massachusetts Department of Public Health.

administered skillfully, and the special instruments and equipment that may be necessary are available. Even a newborn baby will tolerate an abdominal operation of considerable magnitude. Indeed, a group of conditions seen in the newborn must be treated immediately by successful operation if the infant is to survive. These include certain errors in development prior to birth which result in inability to take or to retain nourishment. 'Diaphragmatic hernia' or so-called 'upside down stomach' and the several forms of obstruction of the intestinal tract are examples.

Not immediately but a few weeks after birth a peculiar form of obstruction to the outlet of the stomach is seen fairly often. The fundamental cause is not known but the effect is that the infant nurses hungrily only to vomit all the feeding within a few minutes. Untreated, these patients lose or fail to gain weight and present a pitiful appearance of emaciation as they hungrily cry for the food they cannot retain. In hospitals interested in such patients where large numbers are treated surgically, ninety nine out of a hundred are permanently cured by operation on the stomach.

Somewhat later, at about the sixth or seventh month of life, the largest number of cases of intussusception or telescoping of the intestine into itself occurs. Although this serious surgical emergency may be seen at any age curiously enough, it is much commoner in infants. Usually, there is sudden onset, with evidence of severe colicky pain causing the baby to draw his legs up, cry out and often become very pale. The pain comes at intervals with intervening periods of apparent well being, and mucus and blood may later be passed with the stool. Promptly recognized and operated on within twenty four hours of onset, practically all these patients may be saved but when there is delay the loss of life mounts tragically with the duration of the attack.

At all ages, hernias or ruptures of several types are seen, and the young patient is no exception. Nonoperative treatment is not likely to result in cure, and the mere existence of a hernia constitutes a threat of serious complications to any nothing of the inconvenience and discomfort that may be present. Some are inclined to temporize and delay operation for these patients but there is no reason why a baby or child who is otherwise well cannot be cured surgically at almost any age. The end results of operation for hernia appear to be better when operation is performed in early rather than in adult life.

In general one may say that the need for surgery results from one of several causes: errors in development of which the digestive tract obstructions and hernias are examples; injuries requiring surgical treatment—the abdomen may be the site of such an injury; automobile accidents, falls and injuries in schoolboy athletics that require operation for the repair of an injured organ or for the control of bleeding; although the relatively sheltered life of the young makes such accidents uncommon and infections of the peritoneum or membrane lining the abdomen and covering the several organs. Thanks to the discovery of chemical methods of treatment within the last few years there has been great improvement in the results of treatment and many lives are saved that would otherwise have been lost.

Surgery may also afford the only chance of relief from tumors. Some of the tumors produce mechanical effects, which may be relieved dramatically by surgical removal. It will perhaps surprise my listeners to learn that young persons may be the victims of cancerous growths but some of the most malignant tumors recognized are seen in the young. Certain of these are re-

moved by abdominal operations, and the urgent need of early recognition and treatment cannot be overemphasized.

It sometimes happens that the most careful examination and x-ray and other studies do not suffice to determine a diagnosis of conditions affecting the abdomen and its contents. An exploratory operation to permit actual visualization and handling of the organs may be desirable. Such a procedure, if recommended, should not be a reason for dread or great concern. It is safe to say that a properly conducted exploration in itself is accompanied by very little risk to health, and much may be gained by the determination that conditions are normal or by finding and correcting an abnormality.

No discussion of the subject would be worth while unless emphasis was placed on a condition that is most commonly the reason for abdominal operation and unfortunately and unnecessarily occupies a very important place in the list of causes of death in the young. I say unfortunately and unnecessarily because, ideally, no child should suffer a long illness or have his life jeopardized by appendicitis. To reach the ideal, two things are necessary: prompt diagnosis and early operation. Study after study from surgical clinics throughout the country has demonstrated that with early diagnosis and operation there is almost no loss of life, but with delay and the development of complications the picture is very different. Studies from several large clinics interested in the surgical problems of early life have also demonstrated that, aside from the difficulties in diagnosis, there is nothing peculiar to the young that should result in a high death rate from appendicitis. The same excellent results can be obtained in the young that can be obtained in adults provided three conditions are fulfilled. These are as follows: no cathartics or laxatives for children with undiagnosed abdominal pain, prompt medical observation for any child who complains of abdominal pain for more than an hour or two and prompt acceptance of the operation recommended if a diagnosis of appendicitis is made.

In my opinion, there is little place for the use of laxatives and cathartics, and they should never be employed for a young person with abdominal pain unless it is definitely known that appendicitis is not the reason for the pain. Such medication for a patient with appendicitis may well lead to early rupture of the appendix, which carries with it a number of very serious complications.

Appendicitis is a treacherous disease particularly in the young. It may occur at any age, even in infancy, and, after the first few years of life, becomes increasingly frequent until the age of twenty to thirty. It is particularly treacherous in children for three reasons because it is not thought of as a possibility, because it may be difficult to diagnose early, and because it often develops more rapidly in the young than in those who are older. It may occur coincidentally with or perhaps be related to certain infections such as colds, sore throats, measles and chicken pox, and its early symptoms of abdominal pain and vomiting are the common symptoms of many acute infections in childhood. There is only one safe rule and that is to regard the symptoms of abdominal pain and vomiting as possibly indicating appendicitis until competent medical opinion rules out this diagnosis.

Although most cases follow a pretty definite series of symptoms, there is still a wide variation that calls for careful thought and interpretation if a diagnosis is to be made before there are serious complications. Unfortunately, it is not possible to set forth a series of iron-clad rules to protect from disaster but it is worth while to

point out the usual symptoms and to correct certain misconceptions that experience has shown to be prevalent.

There need not be previous attacks or premonitory symptoms. The best time for operation is early in the first attack. It is seldom, if ever, wise to wait and see if the attack will subside—occasionally it may, but the risk is too great to accept. Appendicitis cannot be "frozen out" by an ice bag; indeed, only surgical treatment need be considered. The existence of some other condition, such as a cold, measles or chicken pox, does not mean that the child does not also have appendicitis. The pain need not be severe,—frequently it is, and this is fortunate, since it usually results in attention to the abdomen,—but often the pain is annoying, grumbling and persistent rather than severe and excruciating, and occasionally there is no complaint of pain at all. There is usually very little fever, commonly between 99 and 101°F., but this is subject to variations from a normal level up to 103°F. Again, abdominal tenderness is usually but not always apparent on examination, generally in the right lower part of the abdomen; however, it may be elsewhere, and any tenderness anywhere in the abdomen is always very significant. Sometimes, the tenderness is evident only after the physician has made an examination of the rectum. Vomiting almost always occurs after the onset of pain, but may precede pain or may be totally absent. A count of the white blood corpuscles is usually desirable to establish the diagnosis, but may be unnecessary—this is a matter for the physician to decide.

Finally, if your physician recommends operation for your baby or child, accept his advice with the assurance that there are many good reasons for such operations, and that under proper conditions the risk is very slight, and negligible when compared with the risk of withholding operation.

## MISCELLANY

### CONSERVATION OF SCHOLARLY JOURNALS

In 1941, the American Library Association created the Committee on Aid to Libraries in War Areas, headed by John R. Russell, librarian of the University of Rochester. The committee is faced with numerous serious problems and hopes that American scholars and scientists will be of considerable aid in the solution of one of these problems.

One of the most difficult tasks in library reconstruction after World War I was that of completing foreign institutional sets of American scholarly, scientific and technical periodicals. The attempt to avoid a duplication of that situation is now the concern of the committee.

Many sets of journals will be broken by the financial inability of the institutions to renew subscriptions. So far as possible, they will be completed from a stock of periodicals being purchased by the committee. Many more will have been broken through mail difficulties and loss of shipment, while still other sets will have disappeared in the destruction of libraries. The size of the eventual demand is impossible to estimate, but requests received by the committee already give evidence that it will be enormous.

With an imminent paper shortage, attempts are being made to collect old periodicals for pulp. Fearing this possible reduction in the already limited supply of scholarly and scientific journals, the committee hopes to enlist the co-operation of subscribers to the *Journal* in preventing the sacrifice of this type of material to the pulp demand.

It is scarcely necessary to mention the appreciation of foreign institutions and scholars for this activity.

Questions concerning the project or concerning the value of particular periodicals to the project should be directed to Wayne M. Hartwell, Executive Assistant, Committee on Aid to Libraries in War Areas, Rush Rhees Library, University of Rochester, Rochester, New York.

### RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR JANUARY, 1942

DISEASES	JANUARY 1942	JANUARY 1941	FIVE YEAR AVERAGE*
Anterior poliomyelitis	2	0	1
Chicken pox	2275	1574	1861
Diphtheria	14	9	20
Dog bite	591	511	551
Dysentery, bacillary	6	3	13
German measles	130	63	60
Gonorrhea	357	263	376
Measles	1018	1887	1885
Meningitis, meningococcal	11	3	6
Meningitis, other forms	9	6	—
Mumps	2231	836	701
Paratyphoid infections	7	5	2
Pneumonia, lobar	390	1052	733
Scarlet fever	1401	596	819
Syphilis	417	296	414
Tuberculosis, pulmonary	222	269	299
Tuberculosis, other forms	19	27	26
Typhoid fever	8	4	6
Undulant fever	1	5	4
Whooping cough	1111	1076	1041

\*Based on figures for preceding five years

### GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Pittsfield, 2, total, 2.

Diphtheria was reported from: Billerica, 1; Boston, 3; Chelsea, 1; Fall River, 4; Lowell, 2; Shrewsbury, 1; Somerville, 1; Springfield, 1; total, 14.

Dysentery, amebic, was reported from: Marblehead, 1, total, 1.

Dysentery, bacillary, was reported from: Camp Edwards, 1; Salem, 1; Tewksbury, 3; Waltham, 1; total, 6.

Encephalitis, infectious, was reported from: Fort Devens, 1; Wellesley, 1; total, 2.

Lymphocytic choriomeningitis was reported from: Winchester, 1; total, 1.

Malaria was reported from: Cambridge, 1; total, 1.

Meningitis, meningococcal, was reported from: Amesbury, 1; Beverly, 1; Boston, 1; Cambridge, 1; Danvers, 1; New Bedford, 2; Norwood, 1; Springfield, 2; Winchendon, 1; total, 11.

Meningitis, other forms, was reported from: Boston, 5; Cambridge, 1; Greenfield, 1; New Bedford, 1; Reading, 1; total, 9.

Paratyphoid infections were reported from: Boston, 1; Gardner, 2; Malden, 1; Quincy, 2; Reading, 1; total, 7.

Septic sore throat was reported from: Barnstable, 1; Boston, 4; Burlington, 1; Cambridge, 3; Fall River, 1; Falmouth, 1; Gloucester, 1; Hanover, 1; Medford, 1; Newburyport, 1; Westford, 1; total, 16.

Tetanus was reported from: Fall River, 1; Springfield, 1; total, 2.

Trachoma was reported from: Boston, 1; total, 1.

Trichinosis was reported from: Cambridge, 1; Lakeville, 1; total, 2.

Typhoid fever was reported from: Bellingham, 1; Boston, 4; Gardner, 1; Waltham, 1; Worcester, 1; total, 8.

Typhus fever was reported from: Arlington, 1; total, 1.

Undulant fever was reported from: Boston, 1; total, 1.

Mumps continued to show a record high incidence for the seventh consecutive month.

Chicken pox, meningococcal meningitis, German measles, scarlet fever, typhoid fever and whooping cough were reported above the five year averages

Bacillary dysentery, diphtheria, measles, pulmonary tuberculosis, other forms of tuberculosis and undulant fever were reported below the five year averages

Lobar pneumonia showed a record low incidence for the second consecutive month

The focus for animal rabies that has been noted in the northeastern section of the State is still active in Middlesex County, cases having been reported from Burlington, Woburn, Danvers and Tewksbury

## REPORT OF MEETING

### NEW ENGLAND PATHOLOGICAL SOCIETY

A meeting of the New England Pathological Society was held on October 16, at the Boston Lying in Hospital Dr Earle B Clarke presided

The first paper, 'Morphologic Findings from Endometrial Biopsy from 100 Cases of Bleeding during the First Trimester of Pregnancy and from 34 Cases of Puerperal Pyrexia,' was presented by Dr Robert N Rutherford Application of the technic of endometrial biopsy to the problem of bleeding in the first trimester of pregnancy in 100 consecutive bleeding cases in the Out Patient Department of the Boston Lying in Hospital has evolved as a simple safe, quick procedure for the detection of the inevitability of abortion This is based on the high incidence of pathologic ova in which the embryo is absent or very defective and which form the bulk of spontaneous abortions in the first trimester The embryos in such specimens tend to die or cease developing, on an average six weeks before actual extrusion at the usual 'lamentable miscarriage' Fetal death or lack of fetal development initiates thrombosis, necrosis and hemorrhage within the decidua and beneath the placental plate, probably on the basis of slow withdrawal of the pregnancy corpus luteum hormone These changes are irreversible, and are easily recognizable as characteristic, even on frozen section Such a finding precludes any need for hormone treatment or restriction of the patient's activities, for Nature is rid of the uterus of defective human materials The procedure carries no danger to a normal pregnancy up to the fourteenth week Its diagnostic accuracy is very high in the 100 cases so studied, 50 were associated with pathologic ova, 42 with defective implantation or defective placental development and 2 with ectopic pregnancy, 6 patients were not pregnant Progesterone in massive doses was of no value in either major problem—defective fetal development or defective implantation, with or without placental or appendage fault

The technic has also been used to study the regeneration of the uterine mucosa following normal full term delivery and spontaneous abortion It has been demonstrated in 25 post partum cases that regeneration is complete within two or three weeks following delivery, that ovulation takes place about six weeks after delivery, but that lactation inhibits ovulation for varying periods Following spontaneous abortion, regeneration is complete in the ideal case in five to seven days, ovulation occurring fourteen days after a curetted abortion Failure to curette, or heavy preabortion progesterone therapy or retained placental fragments will not delay regeneration, but will delay resumption of the normal ovarian cycle Routine immediate postabortion curettage is recommended Subsequent impregnation can take place within two weeks

after abortion, and curettage is recommended as a time saving procedure in difficult sterility problems

In the discussion, Dr Somers H Sturgis stated that Dr Rutherford had shown that a biopsy of the lower uterine segment can be done without precipitating abortion It must be emphasized, however, that such a result cannot always reasonably be expected in less experienced hands The procedure certainly is never justified in the diagnosis of normal pregnancy Interpretation of the material is as significant as the method of taking the biopsy It would take a great deal of confidence for most physicians to empty a uterus on the frozen section findings without waiting for permanent sections However, it is possible to diagnose a nonviable fetus on frozen section of the decidua alone Dr Sturgis entirely agreed with Dr Rutherford's conclusions regarding the futility of progesterone treatment of bleeding cases by calling attention to the uselessness of giving this hormone to cases that already show irreversible, degenerative decidual changes He wondered, however, whether it might not be worth while to give 10 mg of this hormone as a routine, prior to taking the biopsy This might render the uterine muscle temporarily refractory and thus give a certain amount of protection to cases with an unaffected fetus Sometimes, a biopsy initiates uterine cramps, and if this protection were used, an occasional calamity might be averted

With respect to the second part of the paper on the regeneration of uterine mucosa following abortion and delivery Dr Sturgis stated that Dr Rutherford deserves a great deal of credit for his careful histologic examination of daily specimens of post partum endometrium So far as he knew, no such study had previously been performed to throw light on the state of the endometrium during regeneration after spontaneous abortion and after normal delivery in both lactating and nonlactating mothers A comparison of his results in these three groups reveals that endometrial regeneration after spontaneous abortion and curettage is complete in about one week, with evidence of ovulation by the fourteenth day and normal menses on the twenty eighth day Such an immediate return to the normal cycle is not unexpected It may be ascribed to an immediate release of the follicle stimulating hormone of the pituitary gland, previously inhibited by the high titer of estrogens produced by the products of conception A similar immediate release follows estrogen withdrawal under other circumstances For example, at the Massachusetts General Hospital, Dr Sturgis and his colleagues have inhibited the pituitary gland and suppressed the ovarian cycle for about three weeks in a large group of patients with dysmenorrhea It is notable that in these patients, as in women who have spontaneously aborted and who have been curetted, ovulation apparently occurs in about two weeks, and a normal period almost invariably about twenty-eight days after the estrogen has been abruptly withdrawn On the other hand, Dr Rutherford has noted that this prompt pituitary reactivation, with consequent ovulation, does not necessarily occur if curettage is not performed after spontaneous abortion In one of his cases, in which all the products of conception were identified so that no curetting was done, a biopsy on the thirty fifth day still showed regressing decidua The patient apparently had not ovulated Dr Sturgis was tempted to speculate on the possible role of retained decidua on the storage or metabolism of estrogen and its possible effect on the pituitary

In the other two groups of patients,—the nonlactating

and the lactating mothers,—Dr. Rutherford finds regeneration complete in about twelve days. This interval is what one might expect in comparison with that of seven days after abortions under three months. In the non-lactating mothers, as well as in some that lactate, ovulation did not occur in his cases for six weeks. The exact role of the lactogenic hormone in suppressing gonadotropic activity is not precisely known. Failure to lactate, however, does not necessarily indicate a subnormal production or absence of the lactogenic hormone. The trouble may lie in unresponsive breast tissue. It seems likely that production of lactogenic hormone post partum in some way represses the output of follicle-stimulating hormone for three to four weeks. If the mother does not or cannot nurse her child, the gonadotropic activity of the pituitary gland is released at that time, as evidenced by ovulation at about the fifth or sixth week in some cases. In many lactating mothers who continue nursing, however, the stimulus from suckling in some way continues the output of lactogenic hormone and the consequent repression of follicle-stimulating hormone. Dr. Sturgis considered the chief value, perhaps, of Dr. Rutherford's work to be in presenting clear evidence that, during the period of lactation amenorrhea, the endometrium is proliferative—in a relatively resting stage. Amenorrhea at this time, then, is associated neither with persistence of the corpus luteum of pregnancy nor with any new corpus luteum maintained by lactogenic hormone. A regenerated endometrium remains resting until the pituitary gland finally breaks through the inhibition of the estrogens of pregnancy and of the lactogenic hormone, and not till then does the normal four-week cycle of proliferation and secretion start.

The second paper, "Bilateral Cortical Necrosis of the Kidney: A report of two cases with some observations on the pathogenesis and evolution of the renal lesion," was presented by Dr. Walter H. Sheldon.

Two cases of symmetrical cortical necrosis of the kidney following toxic separation of the placenta were presented. The renal lesion consisted of necrosis in the wall of the afferent arteriole at the point where the vessel enters the glomerulus. This necrosis, which in most cases was associated with thrombosis and followed by retrograde extension in the intralobular and interlobular arteries, led to ischemic necrosis of the kidney. Similar lesions were found in the anterior lobe of the pituitary gland, in the pituitary stalk and in the tuber cinereum, as well as in the decum and adrenal gland.

Dr. Foster Kellogg, commenting on the clinical aspects of cortical necrosis of the kidneys, emphasized the difficulty in making the diagnosis clinically. He reviewed a series of cases with oliguria or anuria in association with toxemia of pregnancy or premature separation of the placenta, and concluded that if a patient with premature toxic separation fails to pass much urine in the first two or three days it does not signify definitely that she has cortical necrosis. It is perhaps better to force fluids and go on the assumption that she does not have cortical necrosis and may live, rather than to assume that she has cortical necrosis and is bound to die.

Dr. Richard Wadsworth stated that in a recent report he observed degenerative changes in the hypothalamus following sclerosis of the anterior lobe of the pituitary gland, in addition to lesions in the corpus callosum. He asked whether any degenerative cell changes were seen in either the optic or supraoptic nuclei of the hypothalamus, but Dr. Sheldon replied that he had looked specifically in these regions and found none.

Dr. Sheldon's remarks about the limits and distribution of the infarcted areas in the pituitary gland interest Dr. George Wislocki, who stated that the areas of infarction corresponded to the distribution of the superior hypophyseal arteries,—as investigated by him in the macaque monkey,—including the median eminence of the tuber cinereum, the pituitary stalk and the anterior lobe. The remainder of the tuber cinereum and the posterior lobe showed no infarction because, in Dr. Wislocki's opinion, their blood supplies derive from other sources, namely from hypothalamic branches independent of the pituitary gland, and from the inferior hypophyseal arteries. He suggested that when infarction of the stalk occurs, one should anticipate eventual damage to the hypothalamic hypophyseal tracts traversing the stalk, with related symptomatology.

The third paper, "Relation of Ovarian Stromal Hyperplasia and Thecoma of the Ovary to Endometrial Hyperplasia and Carcinoma," by Drs. George V. Smith, Le C. Johnson and Arthur T. Hertig, was read by Dr. Johnson. Changes occurring in nonfollicle-bearing, postmenopausal ovaries appear to be frequently associated with hyperplastic, bleeding endometria. These changes are characterized by masses of dense, well-vascularized stromal tissue in either the cortex or the medulla of the ovary, with a tendency to form whorls. Some of the stromal cells along capillaries in these whorls become large fat-containing polyhedral cells and look like cells of the theca interna. To these changes, the term "stromal hyperplasia" has been given. When large numbers of such cells form a nucleus, there tends to be some infiltration of lymphocytes and macrophages in the area, associated sometimes with cholesterol-like slits. At such times, foreign body giant cells surrounding the cholesterol slits mark their appearance. To these focal collections, the term "cortical granulomas" has been given. As both stromal hyperplasia and cortical granulomas pass the peak of the anatomic activity, collagen is laid down, and finally on a nest of whorled, hyalinized fibrous tissue remains. The almost constant association of these lesions with hyperplastic bleeding endometrium suggests that there may be a more than coincidental relation between the fat-cholesterol slits and estrogen production.

These changes are very similar to the whorling, vascularity, fat deposition and finally collagen deposition seen in thecomas, and in mixed theca-granulosa-cell tumors. There is also a close parallel between the polyhedral theca-interna-like cells in these lesions and similar cells in the theca-granulosa-cell group of tumors. Of such tumors seen at the Free Hospital for Women through 1935 as reviewed by Dr. Smith, 16 per cent were associated with carcinoma of the uterus. In a paper recently published, he observes that of 180 cases of postmenopausal carcinoma of the uterus during the same period, 87 per cent were associated with excessive amounts of ovarian stromal activity as judged by the quantity of whorled, vascular, stromal tissue, cortical granulomas and polyhedral theca-interna-like cells. This degree of stromal ovarian activity is much greater than that in a series of ovaries from prostatic patients over two years past the menopause who had had a normal menstrual history and no postmenopausal bleeding. Thus, there appears to be anatomic evidence of hyperestrinism in the ovary, in the form either of tumor or of evidence of increased stromal activity—in many cases of carcinoma of the uterus.

The discussion was opened by Dr. Smith, who stated that he was first impressed with hyperplasia of the stromal or thecal cell about six years ago, when combining the

pathological files of the Free Hospital for Women for granulosa cell tumors and cystadenofibromas. During this review, it became evident that the cystadenofibromas were associated with postmenopausal bleeding and endometrial proliferation, although of a degree not so marked as that in cases with granulosa-cell tumors. Until two years ago, however, thecal-cell hyperplasia was to him only an interesting observation. No correlation with other pelvic lesions was evident. At this time, he began reviewing pathology for a paper on cancer of the endometrium, and the frequency of thecal cell hyperplasia in cases with this type of cancer was immediately apparent. Eighty-seven per cent (156 cases) of the postmenopausal ovaries (180 cases) had what was interpreted as slight to marked thecal-cell activity. Sections of endometrium were available from 62 of this group, and 48, or 77 per cent, showed more or less proliferation, mostly less. Dr Smith was unable to correlate the amount of thecal cell hyperplasia with the amount of endometrial activity. Endometrial hyperplasia has for some years been considered a possible forerunner of later endometrial cancer. This idea received support from the findings by Dr Smith and others, of a relatively frequent association between granulosa-cell tumors and carcinoma of the endometrium. About one fifth of his patients with granulosa cell tumors after the menopause also had endometrial cancer. Conversely, of 180 postmenopausal patients with carcinoma of the endometrium seen before 1936 whose ovaries had been sectioned 5 or 27 per cent, had granulosa cell tumors. If he includes those with marked diffuse thecal-cell hyperplasia and those with cystadenofibroma, the percentage of cases of endometrial carcinoma with unmistakable microscopic ovarian activity becomes 8. Compared with the control group of postmenopausal ovaries from cases of prostatic carcinoma which Dr Johnson and he examined together, 90 per cent of the group with carcinoma of the endometrium had significant microscopic ovarian activity, ranging from slight thecal-cell hyperplasia to actual granulosa-cell tumor. He would be more excited about the former if the available sections of endometrium had shown more convincing evidence of estrogenic stimulation. Perhaps lesser grades of thecal-cell activity yield subthreshold amounts of estrogenic steroid for the endometrium. Perhaps, also, it is wrong to assume that thecal-cell activity indicates the production of only an estrogenic steroid. For the present, all that can be submitted is that based on microscopic study, cessation of menstruation does not necessarily mean that the ovaries have ceased functioning.

The last paper, "Observations on a Series of Early Normal and Abnormal Human Ova Obtained prior to the First Missed Menstrual Period," by Drs Arthur T. Hertig and John Rock, was presented by Dr Hertig. A series of eight early human ova,—four pathologic and four normal,—discovered incidentally in uteri removed surgically before the first missed menstrual period, was reported.

The ovulation age of the normal ova varies from eleven to sixteen days, and that of the pathologic ova from twelve to thirteen days. The normal specimens, including the youngest human ovum thus far observed, encompass the developmental period just before and just after the formation of the chorionic villi. The uteroplacental circulation has just begun and consists of a series of large anastomosing sinusoids developed from the endometrial capillaries whose finer branches are tapped directly by the eroding trophoblast thereby flooding the trophoblastic lacunae (future intervillous spaces). Hemorrhage into the surrounding endometrium is a constant feature in normal as well as in abnormal cases. Recent hemorrhage—villi-

ble in amount—is also free in the uterine cavity in both normal and abnormal cases, and arises from the defect in the endometrium created by the embedding ovum.

The significance of the pathologic ova lies in the fact that from them can be evaluated certain factors in the pathogenesis of spontaneous abortion. In all four of these specimens, the ovum itself is definitely defective, either because of lack of an embryo or because of some local or general defect in the trophoblastic development. Detailed studies are in progress to determine whether the environment of these ova is significantly different from that of the four normal ova and hence could have caused the ovular defect, or whether the latter is present at such an early stage of development in spite of a normal environment.

In the discussion, Dr Wislocki emphasized the importance of Dr Hertig's preparations, which, he believes, realize the hope of embryologists of discovering and studying the earliest stages of human development. Through the efforts of Drs Hertig and Rock, this goal is well on its way to being attained. Their series contains perfect implantation stages of the eleventh and twelfth days, and since the free blastocyst presumably attaches to the endometrium on the ninth day (as in the macaque), it is anticipated that this small but critical gap in the knowledge of implantation of the human egg will soon be filled.

## BOOK REVIEWS

*Diseases of the Thyroid Gland, Presenting the Experience of More Than Forty Years*. By Arthur E. Hertzler, MD. 4<sup>th</sup> cloth, with 354 illustrations, and 2 color plates. New York: Paul B. Hoeber, Incorporated, 1941. \$8.50.

In his preface, the author states that this book is "no wise a treatise on the thyroid gland. It is merely a record of his studies which now extend over a period of nearly fifty years."

The style is unorthodox but entertaining. The plan of the book, as set forth in the "Table of Contents," the system of classification of goiters, and the illustrations are excellent. The text is confused and confusing, repetitious and sometimes circular in reasoning. Many of the assertions made invite dispute—for example, "Of what the thyroid gland has to do once the body is developed we know less than nothing." It seems to the reviewer that at least something is known about the function of the thyroid gland in the adult organism.

The genesis of this book, the author says, was the criticism leveled by pathologists at his theory of the toxic nature of myxedema. It seems to the reviewer that a not very successful attempt to refute these critics is the chief purpose of this book.

There is much teleologic reasoning and argument by analogy with commonplace mechanisms. Total thyroidectomy is advocated for all goiters, and the claim that myxedema is relieved by such an operation is put forward. There is much discussion of physical changes in the colloid (based exclusively on staining reactions), which leads to disturbed cellular functions. A thesis is maintained for the existence of a degenerative state of the thyroid gland in addition to the "toxic" factor in the production of "goiter heart," a term that is used quite loosely throughout.

The author's plea to regard the basal metabolic rate as an adjunct in diagnosis rather than as an absolute expression of thyroid function is well taken, but is so distorted in its emphasis as to lead to a dangerous disregard of a

procedure that, when competently interpreted, has proved its utility in the general run of cases.

The sections on the surgical pathology of goiter emphasize the lack of uniformity of histologic states as correlated with the clinical picture; the importance of the stage of the disease is appreciated in this relation, and the fact that large cancers grow from small adenomas is reiterated.

The author lays great stress on the relief of such symptoms as tachycardia, nervousness and weight loss by the removal of nontoxic goiters, but he cites a case in which such symptoms were relieved by the removal of a large lipoma of the neck. This case throws some doubt on the relation between relief of these symptoms and thyroidectomy in his cases of nontoxic goiter.

*Health and the Doctors. In: Propaganda Analysis: A bulletin to help the intelligent citizen detect and analyze propaganda.* Vol. IV, Number 11. 4°, 16 pp. New York: Institute for Propaganda Analysis, Incorporated, 1941.

This issue in the series of pamphlets on propaganda analysis is concerned with the efforts of organized groups to influence the public in the type of medical care to be selected. The philosophies, propaganda methods and motives of the various groups are opposed and analyzed. The arguments of the organizations sponsoring outright socialization and state control are presented more favorably than those of any other, and one gains the impression that the editor, wittingly or unwittingly, has himself subtly expressed a viewpoint in support of socialized medicine. The pamphlet is worth reading by the critical student interested in this subject.

*Fatal Partners: War and disease.* By Ralph H. Major, M.D. 8°, cloth, 342 pp., with 13 illustrations. New York: Doubleday, Doran and Company, Incorporated, 1941. \$3.50.

War and disease have always gone hand in hand. Dr. Major has gone through the records of history and brought into the pages of a single volume the chief aspects of medical interest in relation to military combat. The story is an interesting one. Unfortunately, the style in which the book is written takes away from the pleasure of reading; there is evidence of haste in compilation. To the reviewer, the illustrations often seem to be of slight value, and the book cannot be highly recommended on this account. Although the author presents much that is of value, he has not eliminated considerable irrelevant material.

*Vitamin K.* By Hugh R. Butt, M.D., M.S. in Medicine, and Albert M. Snell, M.D., M.S. in Medicine. 8°, cloth, 172 pp., with 39 illustrations, and 14 tables. Philadelphia: W. B. Saunders Company, 1941. \$3.50.

The problems posed by the discovery of the existence and probable importance of vitamin K constituted a challenge that was met forcefully and adequately. This book represents the tremendous strides that can be made in modern research within the compass of a few years once the impetus has been given. As a result of this co-ordinated experimental and clinical research, practical results of great, lifesaving value have materialized. The first portion of the book is devoted to the historical aspects involving the initial studies in hemorrhagic disease of chicks. Then follows a discussion of the chemistry of vitamin K and, finally, of the clinical studies and applications. Conditions unassociated with vitamin K deficiency and hence not influenced by its use are also considered. This small volume

presents an excellent summary of a subject that should be familiar to all physicians. An excellent bibliography is appended.

*Pathology of the Oral Cavity.* By Lester R. Cahn, D.D.S. 8°, cloth, 240 pp., with 165 illustrations. Baltimore: The Williams and Wilkins Company, 1941. \$5.50.

Half of this work is devoted to a description of the pathology of the teeth and jaws, and the remainder to the common lesions involving the soft tissues of the oral cavity.

The book, as its title indicates, is truly a treatise on the pathology of the oral cavity and is especially useful in relating the pathologic tissue changes with the clinical findings in oral lesions.

There is an abundance of illustrations, a few of which are in color. The histopathological plates are especially clear, and the bibliography is brought up to date.

On the whole, the descriptive material is too brief to be regarded as a textbook, but the work can be recommended as a reference to the dental student, to the scientifically minded practitioner of dentistry, and to physicians interested in oral disease.

*Lymphatics, Lymph, and Lymphoid Tissue: Their physiological and clinical significance.* By Cecil K. Drink, M.D., D.Sc., and Joseph Mendel Yoffey, M.Sc., M.F.R.C.S. (Eng.). 8°, cloth, 406 pp., with 50 illustrations and 45 tables. Cambridge, Massachusetts: Harvard University Press, 1941. \$4.00.

The reviewer considers this a work of unique importance that collects material from varied sources to produce a comprehensive and valuable description of the present physiology of the lymphatic system. The authors have personally added a great deal to the knowledge of lymphatics and lymph, and are admirably qualified to produce this monograph, in which their own work and that of others are critically evaluated. They deserve particular commendation for carefully separating fact from speculation in the application of their material.

The book should be read by every physician desiring to keep abreast of significant advances in medicine. Although the biologist and teacher will be fascinated by the basic anatomy and physiology presented, the work should prove at least as interesting and valuable to the practitioner of medicine.

Wide applications of the knowledge of the lymphatic apparatus are presented. The hematologist, for example, will be interested in the discussions of the production and loss of lymphocytes, and the bacteriologist in the material on the transport of viruses by way of the lymphocytes; the internist and surgeon will both find valuable matter on edema and inflammation.

*Sulfanilamide and Related Compounds in General Practice.* By Wesley W. Spink, M.D. 8°, cloth, 256 pp. Chicago: The Year Book Publishers, Incorporated, 1941. \$3.00.

Since the introduction of the sulfonamides as a new chemotherapeutic approach to the treatment of infection a veritable flood of studies has appeared. This small volume endeavors to summarize the principal facts gleaned from the literature. Appropriate attention is directed to the untoward reactions that may be associated with various chemicals. The inclusion of sulfadiazine brings the book fairly well up to date. Those seeking a brief but adequate survey of the sulfonamides will profit from this book.

## EVALUATION OF REGIONAL LYMPH-NODE DISSECTION IN THE TREATMENT OF CARCINOMA\*

GRANTLEY W. TAYLOR, M.D.†

BOSTON

**D**ISSECTION of the regional lymph nodes is carried out as a routine procedure in carcinomas of the breast, the rectum, the colon and the stomach, as part of the radical operation for dealing with the primary carcinoma. Dissections are elective procedures in the treatment of carcinomas and melanomas of the skin, and of carcinomas of the lip, mouth, external genitalia and various other organs and regions. With the object of determining the indications and value of these elective dissections, over 5000 cases of neoplastic disease have been reviewed from the recent experiences at the Collis P. Huntington Memorial Hospital, the Massachusetts General Hospital and the Pondville Hospital.

### *Indications for Dissection*

It may be said at once that dissection is indicated when operable metastases are present. Unfortunately, this simple statement implies that the clinical recognition of the presence of metastases is accurate. However, metastases may be present before the regional nodes become obviously enlarged, and slight enlargements may have innocent causes in many cases. Enlargement of lymph nodes to a size greater than 1 cm. is strong evidence of metastasis, but there is still the possibility that the enlargement is due to inflammation rather than to metastasis. Actually, there is an error in the clinical recognition of lymph node metastases of 15 to 30 per cent, varying with the region involved, the obesity of the patient and the care and experience of the examiner.

Because of this clinical error, it is desirable to determine—from the characteristics and the usual course of the primary carcinoma—the likelihood of lymph node metastasis in a given case. For example, although carcinomas of the lip in general

metastasized in 24 per cent of the cases, it was observed that metastases occurred in only 7 per cent when the primary carcinoma was less than 1 cm. in greatest extent, and in only 6 per cent of the cases with carcinomas of low malignancy. Similar studies of various other cancers confirmed the opinion that the tendency to form metastases is associated with long duration, large size, high grades of malignancy, an invasive as opposed to a papillary type of growth and recurrences at the site of the primary cancer. In the absence of obvious lymph node involvement, it is only by evaluating these aspects of a cancer that one can arrive at an opinion concerning the presence of metastases.

### *Optimum Time of Dissection*

It may be stated at this point that dissection may reasonably be deferred until metastases can be detected. Thus, fewer unnecessary dissections will be performed. When dissection is deferred until the lymph nodes are obviously involved, however, it is probable that some patients with metastases will have lost their best chance for cure as a result of the delay, and that other cases may prove to be inoperable as a result of inadequate follow-up observations. No absolute rules can be laid down regarding prophylactic, as opposed to delayed, dissection. But, when a primary carcinoma is one with little likelihood of forming metastases, in a patient who is not in sufficiently good general condition to withstand operation and who can be depended on to report faithfully for observation, it is reasonable to adopt a policy of watchful waiting. On the other hand, when there is considerable likelihood of metastasis in a patient in good general condition who may find it difficult to report regularly, prophylactic dissection is favored.

It should be unnecessary to insist that cure of the primary carcinoma is a prerequisite to any

\*Presented at the annual meeting of the New England Surgical Society, November, New Hampshire, September 6, 1941.

†Instructor in surgery, Harvard Medical School; associate visiting surgeon, Mass. General Hospital; visiting surgeon, Pondville Hospital.

elective dissection. It is also a matter of experience that the mortality and complications following dissection are minimized if the dissection is postponed until after healing of the site of the primary carcinoma has taken place. Thus, the optimum time for performing a prophylactic dissection is two to four weeks after eradication of the primary carcinoma. When the lymph nodes are already involved at the time the patient is first seen, the interval may be shortened, but the dissection should still be deferred until after treatment of the primary carcinoma. When one follows a policy of watchful waiting, the patient should be examined at least at monthly intervals for a year after treatment of the primary carcinoma, and bimonthly during the second year. In these cases, dissection should be performed at once if involvement of the nodes is detected.

Extent of Dissection

The extent of a regional lymph-node dissection must be based on knowledge of the lymphatic drainage pathways from the area involved in the primary carcinoma, and the known behavior of the carcinoma concerning node metastases. For example, carcinomas of the lip and buccal mucosa rarely form metastases below the level of the omohyoid muscle, and dissections in these cases may therefore be limited to the upper neck. Carcinomas of the external genitalia may form primary metastases along the external iliac vessels as well as in the superficial nodes of the groin; it is probable that a greater number of cures would result in these cases if the radical Basset type of dissection, instead of a superficial inguinal dissection, were employed.

Bilateral dissections are frequently indicated in lesions involving the lip and the external genitalia. In lesions situated in an area of potential lymphatic drainage in more than one direction, such as the shoulder or flank, it may be necessary to carry out dissections of two areas, such as the neck and axilla, or the axilla and groin. Bilateral or multiple dissections should be performed in stages, rather than simultaneously.

Results

In the results obtained by dissection, only those cases are included in which lymph-node metastasis proved to be present. Untraced cases, and patients dying of intercurrent disease, are excluded as inconclusive. A further group is excluded in which failure resulted because of failure to control the primary carcinoma. In these cases, a dissection is obviously futile.

The results of dissection are presented in Table 1. Although these figures have no standing as an

end-result report, because of the exclusions mentioned above, they probably represent what may be accomplished by regional dissections in properly selected cases when metastases are present.

TABLE 1. Results in Cases of Cancer with Dissection of the Involved Regional Nodes.

PRIMARY TUMOR	NO OF CASES	CURES	
		NO OF CASES	PERCENT AGE
Skin	36	12	33
Melanoma	38	7	18
Lip	100	58	58
Tongue	21	9	43
Mouth (other parts)	33	14	42
Vulva	14	5	35
Scrotum	10	2	20
Penis	21	11	52

These results further emphasize the fact that a large number of failures are properly attributable to local recurrence or persistence of the primary carcinoma.

It has been suggested in some clinics that the results of dissection may be improved by the employment of preoperative or postoperative radiation therapy. Although some of the patients in the present group received such treatment, there was no thorough trial of the method. In general, it has been believed that preoperative treatment postpones and complicates the dissection, and that postoperative treatment is of no benefit after a proper block dissection.

Postoperative Mortality

The figures for postoperative mortality as a result of dissection cover all cases, that is, including the figures for those in which dissection revealed no lymph-node involvement and those in which there was eventual failure through a lack of control of the primary carcinoma. When one considered the mortality incident to axillary dissection, it seemed reasonable to include patients subjected to radical mastectomy. The mortality is shown in Table 2.

Detailed analysis indicates that many of these postoperative fatalities might have been avoided.

TABLE 2. Postoperative Mortality in Cases with Dissection.

REGION	NO OF CASES	DEATHS	
		NO.	PERCENT AGE
Upper neck	601	6	1.0
Neck (radical operation)	112	4	3.6
Jaw (resection)	58	5	9.0
Axilla	1224	29	2.4
Groin	260	10	3.8

One of the commonest errors consisted in operating on the primary focus of disease and the regional nodes at a single sitting. Many of the bilateral dissections were carried out in a single

operation. It is hoped that improvements in anesthesia and operative technique, the employment of chemotherapy in cases that develop infection and the performance of multiple operations in stages rather than simultaneously will contribute to a lowered mortality.

### SUMMARY AND CONCLUSIONS

A review of the results of dissection in over 5000 cases of neoplastic disease is presented.

The decision to carry out a regional lymph node dissection in a case of cancer depends on the presence or the likelihood of development of metastases. The extent of dissection depends on the known behavior of the cancer and the anatomy of the lymphatic drainage areas. Prophylactic dissections may be performed in extensive carcinomas of high malignancy, but dissection may be deferred when there is little likelihood of metastasis, provided that the patient can be followed carefully. Control of the primary carcinoma should precede any dissection.

Dissection is capable of curing metastases in a considerable number of cases, with a postoperative mortality rate that should not be excessively high.

264 Beacon Street

### DISCUSSION

DR ERNEST M. DALAND (Boston). Dr Taylor and I are in full accord on all the facts that he has presented. I shall simply emphasize one or two points.

If one postpones a regional dissection, one should keep a very close check on the patient. We have a general rule that these patients shall report every month for the first year, every two months for the second year, every three months for the third year and so on. In private practice one should be equally careful to see that the patients turn up and have their lymph nodes checked. For many lesions like those on the lips, it is perfectly satisfactory to wait.

I agree that lip and neck dissections, or any other type, should be done in two stages. I have given up the idea of doing a V lip and a neck dissection at the same time. The majority of the lymph nodes palpated in the neck at the time that the primary lesion is seen clear up as soon as one gets rid of the primary lesion and the wound heals. In other words, they are inflammatory. If the nodes persist after a few weeks, I think that one should go ahead and do the dissection.

I do believe that a prophylactic dissection should be done in cases of malignant melanoma, when it is possible to say to which nodes the tumor would be likely to metastasize, for example, in the malignant melanomas of the extremities. I encountered a malignant melanoma in the suprasternal notch a few years ago. It was not possible to do a regional resection, since it would have meant dissection of the mediastinum and both sides of the neck, and perhaps the axilla. If one is dealing with a melanoma of the extremities, and they are much commoner there, one should do a radical inguinal and saphenous dissection including the nodes along the iliac vessels, in the

upper extremity, one should do a radical dissection of the axilla.

Inasmuch as Dr Taylor's figures have proved that clinical observation is so very inadequate in revealing whether or not the lymph nodes are involved, one should not trust to palpation, but as soon as the primary lesion has been destroyed, one should go ahead with the prophylactic dissection, if necessary.

If Dr Taylor had not explained his figures as carefully as he did, we might have been deceived by the relative values of neck dissections on lips and tongues. In the table he showed, 58 per cent of the cases with cancer of the lip and positive nodes were cured whereas in cancer of the tongue, 43 per cent were cured. Of course, that does not represent the relative morbidity or mortality in these two types of cancer. In the former, we operate on most of the cases unless there is very deep fixation. In the latter, we tickle really very few of them, since we must wait for the primary lesion to be destroyed. Because we fail in curing the primary lesion in many cases, and because the nodes when we do feel them are so far advanced, we do relatively few neck dissections. Curability of cancer of the tongue is consequently far below that of the lip.

If one does no more than cure a third to a quarter, as Dr Taylor said in his final remarks, I believe that one will have accomplished something. If these cases were seen earlier, the number of cures for metastatic nodes would be raised considerably.

DR ERNEST L. HUNT (Worcester, Massachusetts). At the risk of being accused of reactionism, I want to point out that my discussion deals wholly with the surgical approach and not the radiation approach.

Dr Taylor has rendered a real service in conducting a research that turns the light of experience on the difficult problem of when and to what extent block dissections should be used to head off the extension of malignant growths, and for so concisely stating his findings and conclusions for our guidance.

In our individual experiences, I am sure that we have all made dissections and found the lymph nodes to show microscopical evidence of inflammatory process only. I am equally sure that we have deferred dissection and later had occasion to regret it.

Given a primary lesion with secondary nodes, those which seem inflammatory may harbor cancer, and those which seem cancerous may prove only inflammatory. Hence, I incline to the belief that one should consider persistence of more importance than size, and act on the principle that failure of nodes to disappear entirely within four weeks after removal of a primary focus implies malignancy. Assuming that to be so, one may well ask, is it logical to await the resumption of activity, as manifested by increase in size of the nodes, before taking preventive action? It must also be admitted that quite sizable nodes may escape detection, even by well trained fingers. To be sure, it is comforting to believe that secondary nodes can probably be advantageously removed even when they have attained a diameter of 1.0 cm., but is one justified in waiting for so insidious a process to attain that much momentum before acting to head it off?

Dr Taylor does not mislead us regarding this difficulty, because he points out the 15 to 20 per cent error in recognition of lymph node involvement. To meet that discrepancy, he directs attention to the size and grade of malignancy of the original growth. Although I am in general agreement with the precepts he defines, I wish, nevertheless, to stress the fact that a policy of watchful

waiting entails many circumstantial pitfalls that may be avoided by prophylactic dissection.

Such a pitfall is illustrated by the case of a seventy-two-year-old retired business man who regards himself as a diabetic, tests his urine frequently and is meticulous in diet. Two years ago, he left for Florida in October, conscious of a "cold sore" on his lip, about which he did not think it worth while to invite his physician's opinion, although he was careful to have his urine and blood sugar tested. He returned in May, with an ulcer on the left side of his lip and a surrounding zone of induration about 8 mm. in diameter. No lymph nodes were definitely palpable, although I thought I could feel a tiny nodule less than a rice grain in size, in the submental angle close to the jaw bone. A liberal wedge excision was done, and an excellent cosmetic result obtained. The pathological report was squamous-cell epithelioma of low malignancy. On the eve of his next departure to Florida, in October, 1940, the submental nodule could not be felt, and the lip was perfectly healed. On his return in May, a sizable node was palpable under the angle of the jaw, on the left side, and the submental nodule was definitely palpable. A suprahyoid dissection of the middle and left sides of the neck was done on May 26, 1941. The pathological report was: "Metastatic squamous-cell epithelioma of low malignancy; normal salivary gland."

Here was a very careful man, under the obsession that he was a diabetic, who, in both the primary and secondary episodes, sacrificed valuable time in relation to a lesion that threatened his life, for the sake of a sojourn in Florida to benefit his general health and diabetic tendency. Certainly, one may assume that a prophylactic dissection after the first operation would have been of greater value to him than one done a year later after the growth had become well implanted and actively growing in a node far around under the angle of the jaw.

If removal of regional nodes is accepted as obligatory in cancer of the breast, does not the same principle apply to the lip or vulva, allowing of course for the infection inherent in the situation of the orificial growths?

Considering the nature of cancer, I wonder if we do not rely too naïvely on this matter of grading. I have been asking myself the questions: Does the degree of malignancy depend entirely on the histologic structure of the growth? May not a growth acquire a higher degree of malignancy according to environmental factors, such as persistent irritation, infection, diet and perhaps hereditary factors of susceptibility and immunity? In the case cited above, a growth of low malignancy histologically had a lively invasive quality.

I conclude by voicing the following convictions: When in doubt whether a prophylactic dissection is indicated, and in the absence of serious contraindications, the correct principle is to err on the side of thoroughness and do the dissection as soon as it may be done safely, rather than to be driven to it at some future and less favorable moment.

Too great reliance should not be placed on grading in justification of a negative attitude toward preventive surgical treatment.

DR. DAVID W. PARKER (Manchester, New Hampshire): I agree entirely with Dr. Taylor's conclusions. I therefore do not wish to take up time with discussion, but should like to report briefly a case of squamous-cell carcinoma in a thirteen-year-old boy, which, I think, is worthy of record.

I saw this child for the first time a few days prior to July 15, 1941. A small nodule or papule had appeared on the inner surface of the upper third of the right arm

three or four months previously. He thought that it was probably an infection, and squeezed it. It did not disappear, however, but grew progressively larger. In the middle of June, he consulted a doctor, who thought it was a cyst and opened it. He expressed some bloody fluid, but a sinus persisted and did not heal. There was no pain, but there was localized redness and thickening. On July 15, I excised the nodule and sent it to Dr. Ralph Miller, in Hanover, for examination. The pathological report was as follows:

The specimen consists of a partially formalin-fixed gray-white red-brown, roughened piece of skin, 1.0 by 0.8 cm., covering a flattened gray-brown and red-brown piece of tissue, 0.8 by 0.7 by 0.3 cm., which, on section, reveals a cavity 0.5 by 0.8 by 0.2 cm., filled with soft, dark, brown-red material. Microscopical examination reveals anaplastic squamous epithelial cells lying beneath normal stratified squamous epithelium, with clear cytoplasm, in which are many areas of hemorrhage. Pathological diagnosis: squamous-cell carcinoma (Grade II).

I was unable to find any palpable nodes in the axilla. However, because a definite percentage of involved axillary nodes are not palpable, — a point that has been brought out so effectively in Dr. Taylor's paper, — excision of the axillary contents seemed advisable. This was done on July 24. The pathological report was as follows:

Examination reveals normal lymph nodes. There is no evidence of malignancy. In view of the low degree of malignancy of the original tumor, and the absence of any evidence of it in the surrounding tissue, the prognosis is excellent.

In this case, there was no involvement of the axillary contents, yet I am firmly convinced that the procedure was definitely justified, and should be carried out as a matter of routine in lesions of this type.

DR. TAYLOR (closing): I was afraid that I should upset certain of the orthodox brethren by not coming out more strongly for prophylactic dissection, and I am very grateful to Dr. Hunt for making the point that, if one is in doubt, dissection should be performed. I did not emphasize enough, perhaps, the absolute necessity for control of the patient, if any deferred program is contemplated and dissection is not offered as part of the initial treatment. The difficulty with Dr. Hunt's patient who went off to Florida is the same thing in a higher economic bracket that we see in the clinic when a patient comes to Boston from the outposts of civilization; once he gets back there after the carcinoma is treated, one knows perfectly well that he will never come out of the woods again until he has a massive recurrence. Dr. Hunt's patient would not come off the beach until he had a massive recurrence.

The patient who cannot be controlled and seen at frequent intervals should have the benefit of a prompt regional dissection. How much damage is done by deferring the dissection and waiting until the nodes appear, I cannot say. I tried to determine that in relation to cancers of the lip. Only 33 per cent of the patients in whom the dissection was deferred for longer than six months from the time the lip was operated on were cured, in contrast to those in whom the dissection was done at once, in whom, even in the presence of positive nodes, the cure rate was about 60 per cent.

I think that the group deferred for more than six months contained a good many neglected cases or cases in which the best program was not followed. There may be an optimum time when, even with deferred dissection,

provided the operation is done promptly on the appearance of the nodes, the patient's chance of cure is not jeopardized to a severe degree

The question has been raised whether cancer can be in transit from the primary focus to the regional nodes and, if so, how long it will take to complete its course so that it will all have arrived at the nodes by the time dissection is performed. One of the theories of dispersion of cancer along the lymphatics is the so-called 'permeation theory' early expounded by Dr Sampson Handley, which is the basis for block dissection in cancer of the breast, the ambition being to remove all the intervening lymphatics

There has been a tremendous amount of work and observation concerning the usual method of dispersion of cancer along the lymphatics, it is usually by embolism of carcinomatous fragments in the lymph stream. Cancer cells probably move as promptly as the lymph stream moves, to the regional nodes—the first point at which they are arrested. That means, I suppose, that the maxi-

mum period of transition is measured in hours rather than in longer intervals. However, a number of cancers, notably the melanomas, permeate the lymphatics. We have all seen the blueberry muffin appearance surrounding the primary focus of an excised melanoma, which means that permeation is in progress. Pack of the Memorial Hospital, in New York City, stated that it takes about two weeks for melanomas to travel up the lymphatics to the regional nodes, therefore, one should wait two weeks before doing a regional dissection. I am embarrassed to say that I do not know whether that is true or not.

Ewing has pointed out that cancer of the penis frequently spreads by way of permeation and that is the reason for the proposed radical block dissections, in one stage, of both groins and the primary cancer. This procedure is theoretically ideal, but almost lethal, in that the mortality is so high as to be justified with difficulty. I furthermore, cure of cancer of the penis may be achieved by operation on the penis and, after an interval, dissection of the groins, by separate operations.

## THE USE OF STILBESTROL IN THE RELIEF OF ESSENTIAL DYSMENORRHEA\*

SOMERS H. STURGIS, M.D.†

BOSTON

IN a previous paper,<sup>1</sup> it was pointed out that relief from cramps in so-called "essential dysmenorrhea" could be consistently obtained by treatment with estradiol benzoate. The present paper presents an analysis of comparable results with Stilbestrol by mouth in the same group of patients that responded previously to estradiol given subcutaneously.

Considerable evidence in the recent literature is now available to prove that Stilbestrol is a highly potent preparation. This synthetic substance, administered orally, has been shown to have the same effect as natural estrogens in controlling the symptoms of the menopause,<sup>2</sup> in producing a proliferation of the endometrium and causing "estrogen withdrawal" bleeding after cessation of treatment,<sup>3</sup> in converting the castrate type of vaginal smear into the "estrous" type,<sup>4</sup> and in inducing growth and swelling of the breasts.<sup>5</sup> The convenience of oral therapy, together with the fact that Stilbestrol is many times more potent than any oral preparation of a natural estrogen, prompted me to determine whether it could be used effectively to control the cramps of essential dysmenorrhea.

It must be emphasized that a satisfactory response to estradiol benzoate could be consistently obtained only when such a course was started early enough in the monthly cycle.<sup>1</sup> In a patient with approximately twenty-eight day

cycles, the first injections were given within the first week at least twenty-one days before the expected menses. When endometrial biopsies were taken after estrin therapy that was timed in this way, the absence of a secretory endometrium in these biopsies was considered evidence that ovulation had been suppressed that month. The painless bleeding that followed such treatment was considered to be due to estrin withdrawal. In succeeding months, if no more treatment was given, the cramps inevitably returned. Such suppression of ovulation by estrin was regarded as a secondary effect, the primary effect in these cases being an inhibition of the follicle stimulating hormone of the anterior portion of the pituitary gland. The follicle normally matures and then ovulates about fourteen days before menstruation. This maturation can be prevented only by blocking follicle stimulation at least seven days previously, or twenty-one days before expected menstruation. When estrin treatment was started too late (that is, less than seven days before ovulation or twenty-one days before menses), the follicle matured, ovulation occurred (as demonstrated by a secretory endometrium) and the menses were accompanied by cramps. On this basis, therefore, it may be postulated that the growing follicle is dependent on the production of follicle stimulating hormone normally from about the twenty-eighth to the twenty-first day before menstruation. During this period, treatment with a potent estrogen will inhibit follicle stimulating hormone production and thus delay or suppress ovulation. From the twenty-first to the fourteenth day, however, the follicle appears to be independent of further pituitary stimulation, during this week, an equal dose of estrin cannot prevent progressive follicular development, maturation and ovulation.

The dramatic and complete relief from cramps during the first flow after cessation of a course of estradiol benzoate injections constitutes an ex-

\*From the Ovarian Dysfunction Clinic, Massachusetts General Hospital  
†Assistant Physician, Massachusetts General Hospital

cellent yardstick whereby these young women can evaluate the effectiveness of other therapy.

### METHODS

A group of consecutive patients who complained of disabling cramps every month but showed no organic pelvic disease has been under study in the Ovarian Dysfunction Clinic of the Massachusetts General Hospital for the last four years.

Nineteen patients, all but 1 of whom were under thirty years of age, received both a "control" series of injections of estradiol benzoate and one or more courses of Stilbestrol by mouth. In this analysis of the Stilbestrol courses, the result was considered satisfactory only when the patients were equally free from any cramps in the month that treatment was given. When mild cramps were present, or the pain was said to be "better" but not entirely absent, such a course of Stilbestrol was rated as unsatisfactory.

### RESULTS

Each patient received one course of injections of estradiol benzoate according to the specifications previously established<sup>1</sup> that completely eliminate cramps for one month.\* In each case, the control series satisfactorily eliminated pain during the next flow.

The oral dose of Stilbestrol† was 1 or 2 mg. daily for varying lengths of time, in an attempt to establish the minimum total dosage that would yield consistently satisfactory results.

The 19 patients studied received seventy-nine courses of oral treatment, and cramps were satisfactorily eliminated fifty-nine times. In the remaining twenty courses, pain was present during the flow that occurred immediately after treatment. This therapy, therefore, was satisfactory in preventing pain in 74 per cent of the trials. This figure does not, however, give a true indication of the effectiveness of the drug. In the discussion below, it is pointed out that the failures were caused by misapplication rather than by inefficacy of the medication.

The daily dose of 1 mg., occasionally 2 mg., of Stilbestrol was continued for from ten to twenty-four days. Of the fifty-nine times that such therapy satisfactorily prevented the cramps associated with ovulation, it was continued long enough to be followed by withdrawal bleeding forty-five times. The remaining fourteen courses, or 24 per cent, in the satisfactory group were followed not by a painless flow, but by approximately four

weeks of amenorrhea, concluding in characteristic, crampy menses. This occurred twelve times when the total dosage was from 10 to 17 mg., and only twice on a total dosage of more than 18 mg.

Six injections of 1.66 mg. of estradiol benzoate, totaling 10 mg. in all, was previously established as the amount necessary to cause withdrawal bleeding, and the same effect in the same group could be obtained consistently with approximately 20 mg. of Stilbestrol orally. A rough comparison of the stimulating effect of these two estrogens on the endometrium is thus obtained.

### TOXIC SYMPTOMS

Careful blood studies and liver-function tests after Stilbestrol treatment have been reported elsewhere.<sup>6,7</sup> The majority of these have failed to show physiologic cause for the commonest untoward symptom—nausea or vomiting. Thirteen of the 19 patients in the group under study admitted that they occasionally had mild to moderately severe abdominal distress during treatment, and 5 of these, or 26 per cent of the group, had nausea and vomiting sufficiently severe to make it seem advisable to discontinue therapy.

One patient had headaches during the concluding days of each course of Stilbestrol. Another complained of mental depression. One patient, during a fourth consecutive course of therapy, developed vaginal staining apparently caused by a 2-mm. pedunculated endocervical polyp that presented at the external os. Since previous examinations had failed to show such a polyp and since no similar episode of spotting had previously occurred, it was considered probable that the almost consecutive estrogenic stimulation over four months in this patient might have produced the growth.

### DISCUSSION

#### *Analysis of Failures*

The twenty failures occurred in 11 different patients. Since the doses used were similar to those in the satisfactory courses of treatment, these failures were not due to inadequate dosage. However, in seventeen of these twenty courses, treatment was started too late in the cycle to prevent the impending ovulation, as shown by the fact that the menses occurred less than three weeks after the start of treatment in each. In other words, Stilbestrol was started less than twenty-one days preceding menstruation and less than seven days preceding ovulation in these cases; at such a time, the dose used could not be expected to check the development of the follicle already under way.

\*This dose has been the same for every case in the present series: 1.66 mg. of estradiol benzoate (Progynon B) subcutaneously for six doses starting on the sixth day after onset of flow, and repeated every third day.

†Supplied through the kindness of E. R. Squibb and Sons, New York City.

The three remaining courses that failed were started more than twenty-one days before the next menses. The failure of one course, started twenty-two days before a period, emphasizes the difficulty of any attempt to establish an arbitrary time limit (such as twenty-one days) for a given medication to produce a biologic effect in a group of different patients under variable conditions. The other two courses are diagrammed in Figure 1. Treatment

FIGURE 1. Case D. B.

Six previous cycles, while under observation without treatment, ranged from twenty-seven to thirty-one days in length. One mg. of Stilbestrol daily by mouth was started on the sixth day of the two above cycles. Treatment was continued for fourteen days in A and seventeen days in B. Menses with cramps occurred on the thirty-eighth day in A and on the thirty-ninth day in B. Cause of failure: Medication was started early enough to delay follicle development, but after conclusion of treatment, ovulation must have occurred (O on chart) to explain painful periods nineteen and seventeen days later. In this case, a dose of 2 mg. daily probably would have been sufficient to suppress completely the developing follicle and to prevent, rather than delay, ovulation.

was started thirty-three and thirty-four days, respectively, before the next periods occurred; it is believed that, in these cases, ovulation was delayed, but not prevented, by the medication given.

#### Calculation of Correct Timing of Treatment

In every patient, some variation in cycle length over a number of months is always present. This variation is probably related to the phase of follicle ripening, whereas the luteal phase of about two weeks appears to be the more consistent half of the cycle. Thus, in a cycle of thirty days, ovulation probably occurred two days late, and in one of twenty-five days, ovulation probably occurred three days early. It is on this basis that the so-called "rhythm theory" of conception control is worked out. To avoid intercourse at the time of ovulation, a patient must know from a record of previous cycles the earliest date that ovulation might occur, as well as the latest. A mass of clinical data in which cycle lengths and periods of abstinence have been carefully recorded bears out

in the main the theory of the constancy of the luteal phase of the cycle.<sup>8-10</sup> If one bears this in mind, it is clear that if ovulation is to be prevented by treatment that must be started one week previously, one must take into account the possibility of an early ovulation as demonstrated by previous short cycles. Thus, if a patient has a record of the occurrence of a cycle of twenty-five days, treatment must be started three weeks before this, by the fourth day after onset of the menses.

In the present series, medication was arbitrarily started the sixth to the eighth day after onset of the menses in each case. A later analysis of recorded cycle lengths in the 11 patients who had one or more failures brings out the fallacy of starting treatment according to any arbitrarily determined number of days after onset of flow. In each case, the shortest recorded interval while the patient was under observation before treatment has been counted. The possibility of the recurrence of a similarly short interval should have been considered in planning therapy. The importance of this, however, was not realized at the time. Seventeen times in these patients, a short

FIGURE 2. Case V. F.

Eight previous cycles, while under observation without treatment, ranged from twenty-five to thirty-one days in length. One mg. of Stilbestrol daily by mouth was started on the seventh day of the cycle and continued for two weeks. A period with cramps began on the twenty-fifth day of the cycle. Cause of failure: Ovulation probably occurred on the eleventh day (O on chart). Treatment started on the seventh day was too late to prevent this. With a record of a previous "short" cycle of twenty-five days, treatment should have been started at least one week before such an early ovulation, on the fourth day of the cycle.

cycle was already under way by the time that treatment was started on the sixth to the eighth day of the month. These failures could have been avoided by proper use of the available data.

To obtain suppression of ovulation with estrin consistently in any group of new patients, therefore, a careful record of at least eight consecutive cycles is indicated, just as a similar record is necessary in the calculation of the rhythm method of contraception.

When such a record is not available, treatment may be started on the first or second day of the cycle, to preclude the possible occurrence of the occasional, sporadic short cycle. Occasional occurrences of either

are responsible for the failures in even the most carefully planned rhythm schedules.

Figures 2 and 3 illustrate two of the failures, to emphasize the considerations given above.

### *Estrin-Withdrawal Bleeding*

In the clinical management of these young women, it is appropriate to know the minimum dose of an estrogen that will consistently produce a subjectively normal cycle. This might

FIGURE 3. Case C. E.

Three previous cycles, while under observation without treatment, ranged from twenty-seven to twenty-nine days in length. One mg. of Stilbestrol daily by mouth was started on the seventh day of the cycle and continued for two weeks. A period with cramps began on the twenty-third day of the cycle. Cause of failure: Ovulation probably occurred on the ninth day (O on chart). Treatment to prevent this should have been started at least one week before such an early ovulation, on the second day of the cycle. In this case, the observation period of only three months was inadequate. Occasionally, a short interval such as this may occur without obvious cause, to upset the calculations based on normally regular cycles.

be defined as the occurrence of a painless flow after approximately a twenty-eight-day interval, and therefore involves two distinct estrogenic effects: estrin must be started early enough to prevent ovulation and the cramps with which it is associated; and estrin must be continued long enough to cause endometrial proliferation sufficient to break down into withdrawal bleeding when medication is stopped.

In the present study, approximately 20 mg. of oral Stilbestrol was established as a dose clinically comparable to six injections of 1.66 mg. of estradiol benzoate, totaling 10 mg. with regard to endometrial stimulation over a three weeks' interval followed by withdrawal bleeding about one week later. It is pertinent to inquire whether the interval from the last dose to withdrawal bleeding is characteristic of the amount of estrogenic stimulation, irrespective of the form of medication, or of the type of estrogen used. This withdrawal interval in the present series shows a variability that can be related essentially to differences in individual response to stimulation. Thus, the average interval before bleeding, after six routine estradiol injections, was seven to nine days. Yet in one patient it was after five, six, six, four and six days, and in another it was after nine, nine, eight, ten, eight and nine days. The limits for

withdrawal bleeding after estradiol were from four to ten days. Roughly, the same range, with similar individual differences, held true for the comparable oral doses of Stilbestrol. The limits were from four to nine days, the usual interval being from five to eight days.

### *Clinical Value of Estrin Treatment for Dysmenorrhea*

After four years' experience with intermittent estrin treatment for essential dysmenorrhea, it can be concluded that this type of therapy offers little as a method of permanent cure. During this time, a few patients received at least six to eight months of estrin treatment a year, yet almost all complained of the same disabling cramps, if no estrin was given, as they had before treatment was started. Only 2 patients have distinctly less severe cramps now, if not treated, than before estrin was given. Even this improvement over the course of two or three years may have little relation to hormone therapy, since many young girls spontaneously improve through a similar interval with no treatment at all. Clinical justification for estrogenic medication apparently does not lie in the promise of a cure for cramps.

One might reasonably question whether artificially induced anovulatory flows might not eventually cause permanent damage to the pituitary gland or the ovaries. No patient has been followed for more than four years, and this, of course, is too short a time to make possible a categorical answer. However, one of the striking results of this therapy is the invariable recurrence of characteristic dysmenorrhea when no treatment is given. Indeed, the very fact that 17 of the 19 patients in this series still have their typical cramps when untreated, even following a number of courses of estrin, argues against any permanent effect on the menstrual cycle. Assurance that no permanent harm is done can be found in the conclusions that relief after estrin is temporary and that administration of the drug does not constitute a method of cure.

It may be objected that it is not a sound gynecologic principle to upset regular ovarian cycles in an apparently normal person, even to the extent of a temporary suppression of ovulation. But these patients came to the clinic because of intractable monthly pain. I believe that the regular recurrence of a disabling complaint, no matter how normal the physiologic process with which it may be associated, justifies an attempt at relief.

It is well to emphasize once more the fact that relief from characteristic cramps after estrin when given according to the specifications outlined above is an all-or-none affair. Although partial mitiga-

tion of the pain may often be obtained by giving estrin as well as many other medicines directly before a period, complete absence of cramps is obtained with estrin only when ovulation is suppressed. It has been suggested that essential dysmenorrhea may be defined as menstrual cramps associated with the presence of a secretory endometrium. Differential diagnosis between this and other causes of recurrent abdominal pain can be derived from a test course of estrin therapy. The pain due to essential dysmenorrhea alone can be consistently and completely eliminated by this treatment.

Clinically, the main justification for estrin therapy in young girls with disabling dysmenorrhea straddles the psychologic and the economic aspects of this complaint. The reason that a patient consults a doctor in the first place is that she has been unable adequately to adjust her life to the certain expectancy of one to three days of disabling pain each month. In some cases, this results in a fixation of fear associated with menses, a psychologic complex that may take the form of futile opposition to all phases of life pertaining to the female sex. More frequently, these girls seem to show an immature personality, one that is irrevocably tied to the mother, the source of sympathy and the refuge against facing life during the monthly pain. The psychologic factor in dysmenorrhea so often mentioned in the literature is likely to be the result rather than the cause of the pain. To obtain the confidence of these girls, as well as to give them back some confidence in themselves, a guarantee of a menses free from pain may be the first step toward a better adjustment. Without such confidence, all the general measures that have been found helpful in the past—diet, exercises, routine habits and so on—are likely to be of no avail.

Some young women have been unwilling to take a position with the embarrassing but inadmissible knowledge that they will be inevitably forced to demand a few days' time off each month. Others, while at school, have found their work seriously interrupted by dysmenorrhea. One patient, a college student, had planned her wedding for the day after her graduation. It became clear from the previous regularity of her cycles that she also could confidently predict the onset of two days of completely disabling cramps for these very days. Estrin injections were advised and given. She was able to look forward to her plans free from anxiety. The important catamenia came and went free from cramps. The best chance for a permanent and complete cure of essential dys-

menorrhea appears to lie either in the normal pelvic changes resulting from pregnancy or in some type of surgical procedure. Either solution may have to be postponed for any number of reasons in any given case for six months, one or two years, or indefinitely. It is my belief that estrin therapy is justified as a temporizing measure in many of these cases, and that a patient can safely be offered relief for two months out of every three, for eight months out of each year, for a definitely limited time. The possibility of carcinogenic action contraindicates continuing such therapy indefinitely.

The cost of the natural estrogen in doses sufficiently potent to suppress ovulation is often prohibitive for many of these patients. Stilbestrol is poorly tolerated by about 1 in every 4 patients, but for those who show no untoward signs of sensitivity, the convenience of an effective oral preparation and its low cost appear to make it a valuable adjunct in the treatment of essential dysmenorrhea.

#### CONCLUSIONS

In a patient with essential dysmenorrhea, absence of cramps can be produced as effectively with Stilbestrol as with estradiol benzoate.

A daily dose of 1 mg. of Stilbestrol by mouth for twenty days produced a comparable effect to that produced by six injections of 1.66 mg. of estradiol benzoate, when given according to certain specifications.

To obtain this result consistently, the start of the treatment should be calculated from an accurate record of at least eight consecutive cycles. In a given month, medication should be started at least three weeks before the possible onset of the shortest previously recorded cycle length for that patient.

This therapy primarily inhibits the follicle-stimulating-hormone fraction of the pituitary gland and secondarily suppresses the growth of ovarian follicles, and hence ovulation during the time that treatment is given.

After conclusion of a course of treatment, the normal pituitary ovarian cycle is re-established, with the invariable recurrence in about one month, if no more estrin is given, of typical dysmenorrhea.

In 20 per cent of the patients, treatment must be discontinued because of gastrointestinal complaints.

Estrin therapy for essential dysmenorrhea is of value as a temporary, rather than a permanent, form of relief.

## PYRUVIC ACID STUDIES IN THE PERIPHERAL NEUROPATHY OF ALCOHOL ADDICTS\*

HERMAN WORTIS, M.D.,† ERNEST BUEDING, M.D.,‡ AND NORMAN JOLLIFFE, M.D.§

NEW YORK CITY

PERIPHERAL neuropathy in the alcohol addict is now generally considered to be the result of a nutritional deficiency and more particularly to be related to a deficiency of thiamin.<sup>1</sup> Experimentally, however, peripheral neuropathy in animals has been produced not only with thiamin-deficient diets,<sup>2</sup> but also with diets deficient in vitamin A<sup>3</sup> and riboflavin.<sup>4</sup> The problem is further complicated by the fact that Kolb and his co-workers<sup>5</sup> have recently been able to produce peripheral neuropathy in pigs fed on a diet containing adequate amounts of thiamin, but deficient in various other members of the vitamin B complex.

It is known that the diphosphoric ester of thiamin (thiamin pyrophosphate) is necessary for the proper catabolism of pyruvic acid,<sup>6</sup> and one would therefore expect hyperpyruvemia in thiamin-deficient subjects. In Oriental beriberi, a disease known to include thiamin deficiency, pyruvic acid does accumulate in the body fluids.<sup>7</sup>

Pyruvic acid is a keto acid and therefore a bisulfite-binding substance. Previous investigators<sup>8-10</sup> have frequently used the measurement of the total bisulfite-binding substances to determine the pyruvic acid level of the blood. More recent work<sup>11-14</sup> indicates that this is not justified and that a more specific method for pyruvic acid must be used.

We<sup>15</sup> have previously determined the concentration of pyruvic acid in the blood of 60 normal subjects. The figures varied from 0.77 to 1.16

mg. per 100 cc., the average being 0.98 mg. Blood pyruvic acid levels above 1.30 mg. per 100 cc. are considered abnormally high. The spinal-fluid pyruvate is 70 to 120 per cent of a corresponding blood sample, the average being 82 per cent.<sup>16</sup>

Finally, we<sup>17</sup> have presented evidence suggesting that pyruvic acid is a normal intermediary of carbohydrate catabolism in man. In normal persons, there is a significant rise of pyruvic acid after the ingestion of glucose, reaching a maximum at the end of one hour and returning to the normal fasting level within three hours.

The present study was undertaken to determine whether or not the peripheral neuropathy of the alcohol addict is associated with a deficiency of thiamin. Forty-eight alcoholic patients with "acute" peripheral neuropathy, 25 with "chronic" peripheral neuropathy and 22 chronic alcoholic patients without any evidence of nutritional disturbance were the subjects for this study. Pyruvic acid in the blood was determined by the method of Bueding and Wortis,<sup>15</sup> with the modifications subsequently published.<sup>18</sup> All samples were obtained on subjects fasting and at rest in bed. The method for blood determinations was also used for the spinal fluid, except that the stabilizing medium (monoiodoacetate) was found to be unnecessary. The results are shown in Figures 1 and 2.

Of the 48 cases of acute peripheral neuropathy, 45 showed an elevated blood pyruvate. In 23 of these, spinal-fluid pyruvate studies were done, and in 20 the pyruvate was abnormally high. Of the 25 cases of chronic peripheral neuropathy, all showed a normal blood pyruvate. In 10 of these, spinal-fluid pyruvate studies were done, and only 1 was elevated. The elevation in this case was very slight (1.31 mg. per 100 cc.). Of 22 cases of chronic alcoholism without any evidence of nutritional deficiency, none showed any elevation of blood pyruvate. In 14 of these, spinal-fluid pyruvate studies were normal in every case.

In 14 cases of acute peripheral neuropathy, pyruvic acid curves following glucose ingestion were abnormally elevated and prolonged. The maxi-

FIGURE 1 Determinations of Blood Pyruvic Acid.

A—Normal subjects, B—acute peripheral neuropathy, C—chronic peripheral neuropathy, D—chronic alcoholics without any objective evidence of nutritional deficiency

mum rise in blood pyruvate was not only greater than that seen in normal subjects, but the elevation above the fasting level was maintained for at least four hours. Furthermore, the maximum rise did not occur at the end of the first hour, as in normal persons, but the pyruvate continued to rise in every case, and maximal figures occurred at the end of the second, third or fourth hour. Particular mention must be made of one case of acute peripheral neuropathy with a normal fasting blood pyruvate, and a markedly abnormal pyruvate curve following glucose ingestion. These curves have recently been published elsewhere.<sup>18</sup>

## DISCUSSION

It will be noted that in 45 of 48 cases of acute peripheral neuropathy, the blood pyruvate was elevated. Two of the three subjects with normal fasting blood pyruvates showed no response to thiamin therapy; as a matter of fact, they grew progressively worse, despite very adequate nutritional therapy. These were the only cases in the

FIGURE 2 Determinations of Cerebrospinal Fluid Pyruvic Acid

A—Acute peripheral neuropathy, B—chronic peripheral neuropathy, C—chronic alcoholics without any objective evidence of nutritional deficiency.

entire group that showed no response to vitamin therapy. In the third case, the normal fasting blood pyruvate was associated with a marked abnormality in the pyruvic acid curve following glucose ingestion; the blood pyruvate was of the type that we have seen in 14 cases of acute peripheral neuropathy thus far studied. This may indicate that the pyruvic acid curve following glucose ingestion is a more sensitive index of thiamin deficiency than the fasting blood pyruvate is.

In 3 of these cases, the urinary keto acid excretion after the ingestion of glucose was studied and found to be within normal limits. During this period, the pyruvic acid curve was abnormally elevated and prolonged. This confirms Waelsch's<sup>19</sup> evidence that the origin of urinary keto acid is not related to the carbohydrate intake. It also indicates that urinary pyruvate levels cannot be used as evidence of deficient pyruvic acid metabolism in man.

We wish furthermore to call attention to the fact that these cases of acute peripheral neuropathy are invariably associated with some type of disturbance in cortical functioning.<sup>20</sup> This varies from simple disorientation with memory gaps, through delirium tremens, the Korsakoff syndrome and the Wernicke syndrome.

The Wernicke syndrome is invariably associated with a thiamin deficiency,<sup>21, 22</sup> but evidence has been presented that it is usually the result of a multiple nutritional deficiency.<sup>22</sup> The other encephalopathic syndromes may also be related to specific nutritional deficiencies, but the evidence presented to date is not conclusive.<sup>23</sup>

It is also essential to emphasize the fact that the modalities most seriously involved (touch, position and vibration) in the peripheral neuropathy of alcohol addicts are those which are eventually to be carried in the dorsal columns of the spinal cord. Alcoholic patients frequently show dorsal sclerosis at post-mortem examination. Clinically, the loss of position sense, vibration sense, light touch and plantar dysesthesia may all be duplicated by lesions in the dorsal columns of the spinal cord.<sup>24, 25</sup> It is therefore virtually impossible to tell whether or not any case of peripheral neuropathy in the alcohol addict is complicated by dorsal sclerosis.

These cases not only show involvement of the peripheral nerves, but also are invariably complicated by disorders in cerebral functioning and perhaps also in the functioning of the dorsal columns of the spinal cord. This becomes readily explicable if one realizes that the brain<sup>26</sup> and spinal cord<sup>27</sup> utilize carbohydrate as their preferential foodstuff, and that this utilization is necessarily interfered with if certain enzyme and co-enzyme systems necessary for the proper breakdown of carbohydrate are lacking.

The patients with chronic or residual peripheral neuropathy showed normal figures. These cases include those who had received adequate vitamin therapy without a complete return to normal functioning of the peripheral nerves and persons who had been on hospital diets for some time. It is possible, however, that many of the latter still show an inability to catabolize pyruvic acid properly, under the additional stress of metabolizing ingested glucose. Such studies are now under way. It has been previously suggested that in cases in which thiamin therapy had not been completely successful, irreversible pathologic changes had occurred.<sup>28</sup> These cases in which the metabolic upset had been corrected but nerve involvement persisted seem to confirm this suggestion. On the other hand, such cases may actually have a cer-

tain amount of dorsal sclerosis, and it is quite possible that thiamin therapy is of no help. Finally, many of these cases of so-called "irreversible" peripheral neuropathy frequently show marked improvement if a diet rich in other nutritive essentials is added to the thiamin therapy. Knowledge of normal nerve metabolism is by no means complete, and as additional light is shed on these other factors, it may be that certain cases of irreversible peripheral neuropathy will prove to be completely reversible.<sup>29</sup>

In the 22 cases of alcoholism without involvement of the central or peripheral nervous system, — and without any other evidence of nutritional disturbance, — the pyruvic acid levels in the blood and spinal fluid were normal. These results indicate that elevations in blood pyruvate are related to the nutritional disturbances that complicate chronic alcoholism and not to chronic alcoholism as such.

In addition, we<sup>30</sup> have studied 280 cases of various neuropsychiatric and medical disorders unassociated with any clinical evidence of thiamin deficiency, and all showed normal levels of pyruvic acid in the blood. On the other hand, we have noted hyperpyruvemia in 22 of 35 cases, complicated by marked elevations in temperature and unassociated with any clinical evidence of thiamin deficiency. In these, the elevation in total metabolism may be a result of prolonged fever, which so increases the thiamin requirements of the body that a deficiency occurs, and hyperpyruvemia results. On the other hand, it must be noted that none of these cases had peripheral neuropathy. This suggests either that the metabolic disturbance must exist for some time before peripheral neuropathy occurs or that hyperpyruvemia may be related to other metabolic disturbances in addition to thiamin deficiency. We also wish to emphasize the fact that we do not believe that a normal fasting pyruvate level invariably constitutes evidence of thiamin adequacy, and we recommend that when doubt exists, the patient be subjected to the additional stress of metabolizing ingested glucose. An inability to metabolize this substance properly is further evidence of a deficiency in thiamin.

Our results suggest that acute peripheral neuropathy in the alcohol addict is invariably associated with a deficiency in thiamin. It must be understood, however, that this does not necessarily mean that a deficiency of thiamin is the only cause of peripheral neuropathy in the alcohol addict, and we are quite certain that, in some cases, recovery is markedly expedited if other factors of the vitamin B complex are given in addition to thiamin.

As a matter of fact, Wortis, Wortis and Marsh<sup>31</sup> noted that 18 such patients showed a marked diminution in the vitamin C levels of the blood and spinal fluid. The authors did not believe that vitamin C deficiency was causally related to the peripheral neuropathy, but stated that these findings indicated the importance of nutritional factors in the nervous and mental disorders that complicate chronic alcoholism.<sup>32</sup>

Our results, however, seem to indicate very clearly that acute peripheral neuropathy in the alcohol addict is associated with hyperpyruvemia. One of the recognized causes of hyperpyruvemia is thiamin deficiency. These cases with hyperpyruvemia invariably respond to thiamin therapy with a reduction of pyruvic acid levels to normal. This correction of the metabolic defect is usually associated with clinical improvement, but rarely with clinical cure.

#### SUMMARY AND CONCLUSIONS

Patients with "acute" peripheral neuropathy almost invariably show hyperpyruvemia. This is not true of patients with "chronic" peripheral neuropathy, or of patients with chronic alcoholism unassociated with nutritional disturbances.

In 14 cases of acute peripheral neuropathy in the alcohol addict, the pyruvic acid curve following glucose ingestion was abnormally elevated and prolonged.

Disturbances in cerebral functioning, and possibly in the functioning of the spinal cord, are invariably associated with acute peripheral neuropathy.

The relation of hyperpyruvemia to cases of acute peripheral neuropathy suggests that this disease is associated with a deficiency of thiamin. On the other hand, data are presented to indicate that other nutritive essentials may well play a role in the picture as it is usually seen.

## REGIONAL ANESTHESIA: ITS USE IN OBSTETRICS AND GYNECOLOGY\*

EDWARD G. WATERS, M.D.†

JERSEY CITY, NEW JERSEY

A SERIOUS and circumspect view of the physiologic considerations that surround the production of anesthesia and the anesthetic needs of a patient inevitably impresses one with the indispensability of regional anesthesia.

Before the methods to be used are considered, it may not be amiss to recall that they all require definite anatomic knowledge, and that generally osteologic prominences serve to localize the approaches to the nerves and help visualize the paths they traverse. A knowledge of the peripheral distribution of the nerves supplying the operative field and the involved structures is equally essential in deciding the optimum injection points. For, obviously, the right nerves must be reached in the best location, with an adequate amount of anesthetic solution, to produce a satisfactory type of anesthesia.

### SENSORY NERVE SUPPLY

The female external genitalia receive their sensory nerve supply from the pudendal plexus, through the pudic nerves and the pudendal branches of the small sciatic nerves, which supply the larger part of the vagina, the labia minora and the posterior half of the labia majora. The anterior portions of the labia majora are innervated by the terminations of the ilioinguinal and genitocrural nerves, and infrequently by the iliohypogastric, which originate in the first two lumbar nerves. The perianal tissues and skin are also served by the coccygeal plexus.

The pudendal plexus is formed by the anterior collateral branches of sacral plexus, the fourth and fifth sacral nerves and the coccygeal nerves, in addition to sympathetic-system filaments. The pudendal plexus is really an inferior continuation of the sacral plexus. It divides into visceral and muscular branches, and in it originate the small sciatic and pudic nerves and sacrococcygeal plexus. The visceral branches unite with the hypogastric plexus and sympathetic filaments to form the pelvic plexuses supplying the bladder, the rectum, and the cavernous and uterovaginal plexuses.

The muscular branches, which supply the levator ani, coccygeus and external sphincter ani, af-

ford sensory fibers to the skin over the tip of the coccyx and base of the ischiorectal fossa.

The small sciatic nerve is entirely sensory, arising from the first, second and third sacral nerves, and leaving the pelvis through the great sacrosciatic foramen, runs to the mid thigh, posterior to the great sciatic nerve.

The inferior pudendal nerve leaves the small sciatic nerve at the lower margin of the gluteus maximus muscle, curves below the ischial tuberosity, and passing into the fold between thigh and perineum, enters the deep fascia lateral to the ischiopubic ramus. From there, its terminal branches go to the labia majora and clitoris.

The pudic nerve originates from the second, third and fourth sacral nerves, emerges from the pelvis through the greater sacrosciatic notch, rounds the ischial spine, and re-enters the pelvis through the small sacrosciatic notch. It immediately gives off the inferior hemorrhoidal nerve, and enters Alcock's canal, a fascial compartment on the medial aspect of the obturator internus muscle. It emerges at the inner and forward aspect of the ischial tuberosity and, at the base of the triangular ligament, divides into its terminal branches, the internal and external perineal nerves and the dorsal nerve of the clitoris. The pudic nerve, therefore, supplies the perianal skin and sphincter, the perineum and part of the labia majora, the perineal and external urethral muscles and the clitoris.

The sacrococcygeal plexus, formed by the fourth and fifth sacral and coccygeal nerves, supplies the pericoccygeal skin and tissues forward to the anus.

Thus, it is seen that the nerve supply of the external genitals is derived mostly from the anterior collateral branches of the sacral plexus and the pudendal plexus (lower sacrals) and the coccygeal nerves, with sympathetic-nerve contributions. The lumbar plexus contributes through the ilioinguinal, genitocrural and occasionally the iliohypogastric nerves. To effect anesthesia, one must block all these nerves.

### METHODS OF REGIONAL ANESTHESIA

The region may be anesthetized in several ways: by intraspinal block, the procedure of choice in all fat and difficult women; by sacral block; and by perineal field block.

\*Presented before the Alumni Society of the Boston Lying-in Hospital, March 14, 1941.

From the Margaret Hague Maternity Hospital, Jersey City, New Jersey.

†Assistant clinical professor of obstetrics and gynecology, Columbia University College of Physicians and Surgeons, New York City; division chief, Margaret Hague Maternity Hospital.

### *Intraspinal Block*

It is not my purpose exhaustively to discuss spinal anesthesia, but a few simple facts concerning it may be worth recalling. It differs from other types of central nerve block in that it is subdural rather than extradural. Induction requires puncture of the dura mater and subarachnoid placement of the anesthetic solution. There must be a minimum of local trauma in introducing the anesthetic. This means proper position of the patient, the use of a good flexible needle of small gauge, and avoidance of contact with the periosteum and, especially, with the intervertebral disk and nerve radicles. Adherence to these rules resolves itself into experience and the knowledge of anatomy. Bad results are generally due to lack of fundamental knowledge and inept technic.

Once placed, the anesthetic and its effects are largely beyond control. Hence, the amount and placement level must be conditioned by the patient and the operation to be done. For abdominal, gynecologic and obstetric operations, the level is the third space, with 100 to 120 mg. novocain diluted in spinal fluid to a volume of 3 or 4 cc. In a prolonged case, 8 to 10 mg. of Pontocaine is added. For vaginal work and deliveries, 50 mg. of novocain is similarly diluted and placed intrathecally in the fourth space. The patient is kept flat on the table, or a moderate Trendelenburg position may be used if the patient is not pregnant or if there is no large abdominal tumor, intraperitoneal fluid or marked distention. Ephedrine sulfate,  $\frac{3}{4}$  gr. hypodermically before induction of anesthesia, lessens blood-pressure fall, although this in itself is unimportant provided the pulse remains good and the respirations are not embarrassed. If respiratory embarrassment occurs, immediate inhalation use of oxygen under pressure and intravenous fluids are invariably effective. I have given over three thousand spinal anesthetics, with but one death that could be ascribed to the anesthetic; I admit, however, a few close calls. In the Margaret Hague Maternity Hospital, we have administered over five thousand spinal anesthetics in the past eight years, with three deaths that could be ascribed, with any reason, to the type of anesthetic given. It scarcely needs saying that we should have long since given it up had we found the dangers even remotely as present as its antagonists contend. The vast majority of the detractors of the procedure have had little or no experience with it and possess an inferior technic. We do not claim it to be the 'only anesthetic to use or the best in every case, and it has definite contraindications. But it is a very good and very safe anesthetic when properly employed, and its use

is not infrequently the major factor in a patient's recovery from a difficult plight.

### *Sacral Block*

Unfortunately, the facility of administering a spinal anesthetic has obscured the value of another form of nerve block — trans-sacral, with caudal, block. This is a perfectly safe type of anesthesia that is only moderately difficult to employ. The combination has the virtues of subdural block, with none of the hazards. The objections are the time it takes, frustrating fat and, in pregnancy, inability to obtain the optimum induction position.

Although I admit that sacral block has taken a poor third place to spinal anesthesia and local infiltration in pelvic, perineal and rectal work in my own hands, it is a good type to have in reserve for special conditions. For cases of hypertensive cardiac disease or pre-eclamptic toxemia with respiratory infection, or in any other case in which a spinal anesthesia might be somewhat hazardous or the patient is suffering with an upper respiratory infection of any degree, a sacral block is ideal.

The technic may be rather simply and quickly set down, thanks to the pioneering work of Labat<sup>1,2</sup> and others,<sup>3-7</sup> who have so well standardized its application. If the prone position, with a cushion under the patient's hips to raise the sacrum, is not possible, the next best one is the extreme Sims. Caudal block is first induced, since it takes about twenty minutes for it to be effectively obtained and because it fails in 10 to 20 per cent of cases. For caudal block, the puncture is made in the sacral hiatus in the middle of a triangle formed by the sacral cornua and the fourth sacral spine. The sacral hiatus is palpated with the finger, after which the needle is introduced with the bevel upward at an angle of 20° with the skin. The needle passes through the ligament and forward to the anterior wall of the canal; it is then retracted and depressed 20° farther. It is then introduced as far forward as a line joining the posterosuperior iliac spines. This marks the average lower depth of the dural-sac level. It is essential not to carry the puncture farther, and not to introduce the solution if spinal fluid is then obtained. Thirty cubic centimeters of a 2 per cent novocain solution is injected or if parasacral block is also employed, it is better to use 30 cc. of a 1 per cent novocain solution. I generally add about 5 minims of epinephrine solution, about 0.5 mg. to each 100 cc. of anesthetic employed.

Paravertebral sacral block may then be proceeded with. The landmarks here are the sacral cornua and the posterosuperior iliac spine. As a matter of fact, the point most commonly chosen for the

latter is the regional posterior spine, which is the last prominence at the posterior extremity of the iliac crest, usually about 1 cm. above the anatomic spine. The sites of injection are chosen as follows: wheals are raised 1 cm. medial to and below the regional posterior spine, with another wheal lateral to and just above the sacral cornua; a line, which is drawn between these two points and beyond the posterosuperior spine, is divided between the two chosen points into three equal parts, with two wheals of novocain. The ilial or uppermost wheal marks the aperture of the second sacral foramen. The cornual wheal marks the site of the fifth sacral foramen. The other two wheals, marked out between these, locate the third and fourth sacral foramina. The first sacral foramen is punctured through a wheal raised 3 cm. on the line above the ilial or first wheal. The manner of injection is as follows: The bone is met on the dorsum of the sacrum before the foramen is perforated, and the needle is then passed in for varying distances. It is probably easiest to remember that from the first to the fifth foramina, respectively, the distances that the needle enters after touching the bone diminishes by 0.5 cm.—from 2.5 to 0.5 cm.—for each foramen, and the amount of novocain, a 1 per cent solution being used, diminishes from 6 to 2 cc., being reduced 1 cc. for each foramen. This, then, permits the introduction of 20 cc. of novocain solution on each side of the sacrum in contact with the sacral nerves as they emerge from the anterior surface of the sacrum; the radicles of the sacral and perineal plexuses are thus blocked. Anesthesia here follows very promptly, and by the time of its completion, caudal anesthesia is generally effective if it is to become so.

### *Perineal Field Block*

There are several effective ways of obtaining a satisfactory perineal field block; the one that I routinely employ, which has proved satisfactory, is not claimed to be better than any one of the other methods used, but it has repeatedly given and continues to give satisfactory results.

The principle employed is the blocking of nerves supplying the vulval and perineal region as they approach that area. The main injection involves blocking the pudic nerve as it emerges from Alcock's canal near the ischial tuberosity. The other nerves are blocked as their terminations approach the field. The first injection is made through a wheal raised over the ischial tuberosity. A 10-cm. needle is introduced, and bony contact is first made with the ischial tuberosity; it is then passed 2 cm. medial to and 2 cm. deeper than the tuberosity. This is approximately the point at

which the pudic nerve emerges from Alcock's canal. Fifteen cubic centimeters of a 1 per cent solution of novocain, with ephedrine, is injected at this site on both sides. The needle is then withdrawn, reintroduced and conducted subcutaneously about 0.5 to 1 cm. deep across the perineum to the ischial wheal on the opposite side. It is then withdrawn and directed from both wheals backward toward the anus until injections are made into the sphincter muscle itself. Reintroduced through the ischial wheals, the needle is directed obliquely inward toward the introitus, then deflected sharply upward along the inner aspect of the vestibular bulb and under the labia minora, distending the structures with novocain as far forward as the clitoris. Thus, a diamond-shaped block of the introitus is evolved. The transverse bischial infiltration with the anterior limbs blocks the ilioinguinal, iliohypogastric and genitocrural nerves, the pudendal branch of the small sciatic nerve and, partly, the internal and external branches of the pudic. The posterior arms block the hemorrhoidal branches of the pudic nerve and the terminations of the anococcygeal plexus, and paralyze the anal sphincter. Direct infiltration of the pyramidal perineal body permits immediate, deep, perineotomy.

When the innervation of the external genitals is recalled, it is apparent that not only the sensory but also the muscular nerves of these structures are effectively blocked, and anesthesia is produced for a third or half of the way up the vagina. One must also remember that, even with an outlet-forceps application, the blade tips are far in the vagina, where there is less sensation but also no anesthesia, and anesthesia should therefore be supplemented with deliberate and gentle movements. For deep vaginal work in gynecology, submucosal local infiltration is added, as well as a broad ligament block for cervical procedures, to anesthetize the uterine and vaginal sympathetic plexuses. It is recommended that adrenalin always be added to the anesthetic solution. In obstetrics, the extreme vascularity of the parts causes a rapid washing out of novocain, with anesthetic failure, unless this precaution is taken.

## MEDICAL PROGRESS

### HEMATOLOGY: DISEASES OTHER THAN ANEMIA

WILLIAM DAMESHEK, M.D.\*

BOSTON

#### BONE MARROW

THE sternal bone-marrow biopsy, performed chiefly by means of the simple puncture technic, has become almost a routine hematologic procedure. Not only is it of value in the differential diagnosis of so-called "refractory anemia," "princytopenia" and so forth, but it is distinctly a necessary maneuver in ruling out leukemia in cases of both thrombopenic purpura and hemolytic anemia, especially when splenectomy is being seriously considered. The physician who familiarizes himself with the technic will gradually develop a better understanding of the physiologic pathology underlying the various blood pictures. Since the latter may give only an imperfect reflection of what goes on in the blood forming tissues, careful study of the marrow should be of real help in developing a fundamental knowledge of the blood conditions. To learn "to walk about" in the marrow requires only a little instruction but a good deal of practice and patience. In any event, interpretation of bone marrow pictures is not nearly so difficult as it seems at first glance.

Probably the best monograph thus far on the bone marrow (in German) is that by Rohr,<sup>1</sup> of Zurich, Switzerland.

Recently, the sternal bone marrow has been utilized for therapeutic purposes. Thus, Morrison and Samwick<sup>2</sup> cite the case of a patient with aplastic anemia who was given several injections of normal sternal marrow, totaling 13 cc, obtained from compatible donors. The patient recovered. It is to be noted that just prior to the bone-marrow "transfusion," the patient's blood showed well-defined evidences of increased regenerative activity on the part of the marrow, that is, marked polychromatophilia and the presence of nucleated red cells. Frequent reticulocyte and platelet counts were not performed. Various other forms of therapy, such as liver extract and iron, were also used. It is highly doubtful whether the few cubic centimeters of actual normal bone-marrow tissue

injected into the sternum had any effect on an organ that approximates about 1400 cc. in volume.

Fluids and blood injected into the sternal marrow cavity quickly reach the venous circulation, as demonstrated by Tocantins and O'Neill.<sup>3</sup> These investigators, after a thorough study of the sternal marrow in various age groups, devised a special needle and adapter by which, in an emergency, it is possible to transfuse into the sternal cavity large quantities of blood or saline solution. This might conceivably be important in a case with extensive burns or when the veins are collapsed or inaccessible.

#### FRAGILITY TESTS

The methods in general use for determining hypotonic fragility are quite inaccurate. The method most commonly employed, that of Giffin and Sanford, utilizes unmeasured drops of blood, which are placed in tubes containing only roughly estimated amounts of hypotonic saline solution. In the procedure of Daland and Worthley,<sup>4</sup> the solutions and the amount of blood are accurately measured. Furthermore, the blood is adjusted to constant volume so that even in the presence of severe anemia, approximately the same number of red cells are added to similar volumes of saline solution. Even this method, however, leaves room for improvement, since the tube in which beginning hemolysis is present is often difficult to define and the other readings are also more or less subjective. To avoid these disadvantages, Waugh and Asherman<sup>5</sup> used the Evelyn photoelectric colorimeter and measured the degree of hemolysis directly. By this method, curves of erythrocyte fragility measuring the percentage of hemolysis with the various solutions of hypotonic saline could be drawn. In a later paper, Waugh and Lamontagne<sup>6</sup> illustrated an application of this method in the study of the changes in fragility following splenectomy in congenital hemolytic jaundice. Hunter<sup>7</sup> has recently described a similar method, and Cruz and his co-workers<sup>8</sup> also utilized this method in a unique study with radioactive iron of the effect of age on the susceptibility of the erythrocyte to hypotonic saline solutions. The latter authors injected radioactive iron into dogs rendered anemic by

bleeding. This "tagged" iron is present only in the young red cells, — reticulocytes, — and it was thus thought that an accurate determination of the relative fragility of older as against younger red cells could be made. The surprising result was obtained that the very new red cells in the circulation were "markedly less resistant" to hypotonic saline solutions than the older cells. Unfortunately, this type of experiment probably does not yet completely solve the vexing question whether younger or older red cells are more fragile.

#### BLOOD VOLUME

Gibson has been in great part responsible for perfection of the blood-volume test that utilizes the Evelyn photoelectric colorimeter and the Evans blue dye. In a recent article,<sup>9</sup> a general review of his findings is presented. In the diagnosis and follow-up of a case of polycythemia, determination of the blood volume is often of great value. In studies of hemolytic anemia, the relation of the total mass of hemoglobin to the urobilinogen content of the feces gives an index of blood destruction that is at times of diagnostic value.<sup>10</sup> Although the Gibson-Evelyn method for determining the blood volume is universally conceded to be the most accurate, Ebert and Stead<sup>11</sup> have recently criticized it because the cell-volume reading depends on the hematocrit and this factor is difficult to determine accurately. The latter investigators showed that the relative proportion of red cells varied considerably in different blood vessels of the body, and that the basing of the hematocrit on determinations made from basilic veins might lead to error. This has, of course, been well known, but is difficult to get around, unless some such method as that of Barcroft (utilizing carbon monoxide) is used.

Hahn, Ross and their co-workers<sup>12</sup> have devised another interesting method, which has not yet been applied to human beings. From a dog injected with radioactive (tagged) iron, a known amount of blood is injected in other dogs, and the blood volume calculated from the relative amount of radioactivity present in the injected dog's blood.

#### TESTS OF BLEEDING TIME

The test in use for many years is that of Duke, in which a puncture of the ear is made, the resulting wound being blotted every thirty seconds. Ivy, Shapiro and Melnick<sup>13</sup> attempted to make the test more accurate by pricking the skin of the forearm under conditions of venostasis — a blood-pressure cuff being inflated over the arm to a pres-

sure equivalent to 40 mm. of hemoglobin. In a more recent article, Ivy, Nelson and Bucher<sup>14</sup> report on the standardization of the various factors of pressure, type of puncture, type of blade used and so forth. By this method, the bleeding time varies between sixty-one and two hundred and forty seconds.

#### BLOOD GROUPS

##### *Rh Factor*

One of the outstanding examples of progress in hematology during 1941 has been the development of knowledge concerning the Rh factor. Landsteiner and Wiener<sup>15</sup> showed in 1940 that by the injection of blood cells of the monkey — *Macaca rhesus* — into rabbits, an antirhesus red-cell agglutinin was built up in the rabbit serum. Curiously enough, it was found that this agglutinin (called "anti-Rh") also agglutinated the red cells of most human subjects, without reference to the regular human blood groups (O, A, B or AB). Further studies by Wiener and Peters<sup>16</sup> demonstrated that the cause of certain severe blood-transfusion accidents, involving donors and recipients of the same blood group, lay in the presence of this anti-Rh agglutinin in the recipient, reacting against the donor's susceptible red cells, which contained an Rh binding substance or agglutino-gen; such persons are said to be "Rh+." Levine and his co-workers<sup>17</sup> demonstrated that approximately 85 per cent of 1035 persons were Rh+, and 15 per cent Rh-. Thus, if an Rh- subject (that is, one having no Rh agglutino-gen in his red cells) is given blood from a donor with Rh+ cells, a reaction will occur if the recipient's serum contains the anti-Rh agglutinin. Only an Rh- person can possess anti-Rh agglutinin in the serum, since the two substances are mutually incompatible. It was further found that most of the transfusion reactions involving the Rh factor occurred in women, either pregnant or in the puerperium, who had been given blood from their husbands. Analysis of several of these cases by Wiener and Peters<sup>16</sup> and Levine and his co-workers<sup>17</sup> demonstrated that the recipient was Rh- but had an anti-Rh factor in her serum, and that the husband donor was an Rh+. The possibility was suggested that the mother might have become immunized against her husband's red cells by way of the fetus (which usually was Rh+). The concept of isoimmunization in the human being by the Rh factor was thus developed.

Shortly thereafter, Levine, Katzin and Burnham<sup>18</sup> pointed out that in cases of erythroblastosis foetalis, the following combination of facts was present: the mother was Rh- and often showed

\*Dr. J. F. Ross of the Evans Memorial, Massachusetts Memorial Hospitals, has recently applied this method to human blood-volume determinations by injecting tagged red cells from previously injected polycythemic patients into other persons.

anti Rh agglutinin in her serum, the father was Rh+, and the infant was Rh+. It was suggested by these workers, and borne out by analysis of repeated cases, that some Rh- mothers might become immunized to the Rh factor if the baby's red blood cells passed into the general circulation via the placenta. When this had taken place, an agglutination reaction might occur within the placental tissues, damaging the red cells and producing the clinical picture of erythroblastosis foetalis in the newborn infant. This rather startling although attractive theory of isoimmunization as an explanation of the pathogenesis of the disorder has already aroused a great deal of interest and may be of considerable practical significance.

To test a subject for the presence or absence of Rh factor in the red cells, it is necessary to have anti Rh testing serums. These are not now readily prepared, and reliance must be placed on human subjects who have developed an anti Rh substance in the serum. Since these are relatively scarce and since, furthermore, the actual testing is somewhat more delicate and "tricky" than ordinary blood typing, it becomes essential for the practicing physician to observe the following rules regarding transfusions of blood. In the first place, compatibility tests, particularly with patients who are pregnant or in the puerperium, or who have had previous transfusions, should be performed by the Landsteiner test tube technique. One drop of the serum to be tested, one drop of a 2 per cent red cell suspension and one drop of physiologic saline solution are placed in small test tubes, incubated at 37°C for thirty to sixty minutes, and centrifuged for one minute at slow (500 RPM) speed, and the sediment of the tube is inspected<sup>19</sup> and the tube observed for clumps—a definitely positive reaction is readily observed with the naked eye, and a negative reaction should be checked by microscopic examination of the sediment. Secondly, if a transfusion is required in pregnancy or the puerperium, it is best not to use the husband as a donor. And, finally, in erythroblastosis foetalis, one should go to great lengths in obtaining an Rh- donor for the infant, and in performing exceedingly careful cross-matching tests preliminary to transfusions; the infant's mother should not be used as a donor. The further general suggestions might be made before a transfusion is given, the question whether it is really necessary should be asked, and typing and cross-matching should not be performed by the most inexperienced junior on the service. Correct typing and cross matching before a transfusion are important tests and deserve the utmost care; they are best done by competent unhurried workers.

### Miscellaneous Data

Group A (Type II, Moss) is known to be made up of Subgroups A<sub>1</sub> and A<sub>2</sub>. With the use of high-potency testing serums,\* cells of Group A or Group AB can almost always be distinguished. However, occasional persons of Group A or AB react feebly even to the most potent testing serums and may therefore be miscalled Group O or B. Recently, Wiener and Silverman<sup>20</sup> demonstrated that a third A agglutinin (A<sub>3</sub>) was occasionally present, and might be confusing in determining the blood group. This brings up another possible cause for transfusion reactions, which can be avoided only by very careful compatibility tests.

The preparation of anti M, anti N, anti-A and anti-B testing serums is discussed by Silverman.<sup>21</sup> The difficulties involved in preparing a potent anti-N serum are pointed out. The use of M and N testing serums in the exclusion of paternity is increasing as knowledge of the importance of these factors gradually becomes disseminated. With development of potent A<sub>1</sub>, A<sub>2</sub>, Rh and possibly other factors, it will be possible to increase the percentage of exclusions from the present approximately 40 per cent to a higher figure.
